Physiology moves back onto centre stage: a new synthesis with evolutionary biology

D. Noble

Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK

New developments in evolutionary biology and molecular genetics have far-reaching consequences for physiological science since they imply major extensions or even replacement of the Modern Synthesis (Neo-Darwinism) [1, 2, 3, 4, 5]. The Modern Synthesis was a mid-twentieth century gene-centric view of evolution, based on random mutations accumulating to produce gradual change through natural selection. Any role of physiological function in influencing genetic inheritance was excluded. The organism became a mere carrier of the real objects of selection: its genes. We now know that genetic change is far from random and often not gradual. Molecular genetics and genome sequencing have deconstructed this unnecessarily restrictive view of evolution in a way that reintroduces physiological function and interactions with the environment as factors influencing the speed and nature of inherited change. Acquired characteristics can be inherited, and in a few but growing number of cases that inheritance has now been shown to be robust for many generations. The twenty-first century can look forward to a new synthesis that will reintegrate physiology with evolutionary biology. This lecture will outline the key features of the new synthesis and why it could bring physiology back onto centre stage in biology. “It is hard to think of a more fundamental change for physiology, and for the conceptual foundations of biology in general.” [1]

L2

Pathological development of brain microvasculature

E. Dejana

IFOM, FIRC Institute of Molecular Oncology and Department of Biosciences, University of Milan, Milan, Italy

Brain microvasculature constitute a highly specialized and selective vascular barrier between blood and the central nervous system, called blood brain barrier (BBB). In these vessels endothelial cells present a highly developed system of tight junctions (TJs), absence of fenestration and low pinocytotic activity. Cells of the brain parenchyma, the astrocytes, contribute to the BBB-coverage with their foot processes, which constitute about the eighty percent of the basal aspect of the vessels. As a consequence, circulating solutes do not readily enter the brain parenchyma unless through specific endothelial “transporters”. Thus, BBB also limits the passage of anticancer drugs from the blood to the brain. Therefore, it would be therapeutically useful to develop systems to modulate BBB permeability. To this aim it is important to define the molecular mechanisms that regulate the establishment and maintenance of BBB properties.

Data from our laboratory suggest a key role of the Wnt/β-catenin signaling pathways in the induction, regulation and maintenance of the BBB characteristics during embryonic and post-natal development. In endothelial cells, Wnt signaling induces barrier differentiation by increasing the stabilization and the transcriptional activity of β-catenin. On the contrary, inactivation of β-catenin causes significant downregulation of junctional proteins, and consequent BBB breakdown.

Besides β-catenin, other three proteins, CCM1, CCM2 and CCM3, expressed by brain endothelial cells, are emerging as key modulators of the organization and function of the BBB. Indeed, mutations occurring in any of the genes encoding these proteins, leads to Cerebral Cavernous Malformation (CCM), a pathology characterized by brain vascular malformations. The endothelium in the lesions presents very few tight junctions and gaps are observed between endothelial cells. In addition, the vascular basal lamina is disorganized and the astrocytes do not take contact with the endothelial wall. The structural alterations of the BBB observed in CCM lesions are associated with severe clinical manifestations, such as cerebral haemorrhages and stroke. Additional data point to a possible link between inflammatory cytokines and the function of CCM proteins in the regulation of BBB stability. These data open new therapeutic opportunities for this so far incurable disease

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L3

3R’s: Reproductive Regulation Revised

I. Clarke

Physiology, Monash University, Melbourne, VIC, Australia

The last decade has seen remarkable advances in our understanding of the control of reproduction. In particular, neuroendocrine systems have been discovered that significantly alter the way that we view central control of gonadotropin releasing hormone (GnRH) secretion and action. The recognition that kisspeptin is a potent stimulator of GnRH neurons was a seminal advance. Kisspeptin cells are now seen as the sex-steroid responsive cells that relay feedback information to GnRH cells. In addition, in seasonal breeders, the function of kisspeptin cells is altered in a predictable way between breeding and non-breeding seasons. The finding that kisspeptin cells of the arcuate nucleus also produce neurokinin B and dynorphin add another layer of control of reproduction and this has led to the development of new tools for the manipulation of reproduction. The kisspeptin cells also interact with appetite regulating neurons in the brain and this has furthered our understanding of how metabolic state can influence reproductive function. The question as to whether kisspeptin cells

are the sought after 'pulse generators' for GnRH cells will be discussed.
Another newcomer on the reproductive neuroendocrine stage is gonadotropin inhibitory hormone (GnIH) and the extent to which this is important has been investigated in a variety of species. Compelling data for an inhibitory role in the regulation of reproduction has been obtained in studies on sheep and this will be reviewed.
With the expansion of our knowledge of the reproductive neuroendocrine system, revision of our textbooks is in progress. Kisspeptin provides us with the conduit for communication from the gonads to the GnRH cells and GnIH may play a lesser role as a modulator of GnRH function. In addition, the modulatory role of other neuropeptides, such as the melanocortins, is now appreciated and allows us to formulate models for the multimodal regulation of reproduction by the brain.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L4

Health-promoting effects of exercise in diabetes and obesity: from molecular mechanisms to clinical action

J.R. Zierath

Karolinska Institutet, Solna, Sweden

Insulin resistance is a characteristic feature of Type 2 diabetes mellitus and obesity. Although defects in glucose homeostasis have been recognized for decades, the molecular mechanisms accounting for impaired whole body glucose uptake are still incompletely understood. This lecture will focus on the sites of insulin resistance in Type 2 diabetes and mechanisms by which exercise enhances glucose uptake in skeletal muscle. Epigenetic modifications are thought to play an important role in the development of metabolic diseases. DNA methylation is one form of epigenetic modification linking environmental factors to the control of insulin sensitivity. The first part of this lecture will focus on the role of DNA methylation and insulin sensitivity in type 2 diabetes and obesity. Thereafter, the role of DNA methylation as a regulatory mechanism for gene expression changes in response to exercise will be discussed. Given the importance of lifestyle factors in the development of metabolic disorders, DNA methylation provides a mechanism by which environmental factors, including diet and exercise, play a role on the pathogenesis of skeletal muscle insulin resistance and risk for Type 2 diabetes.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L5

Neuronal calcium channels and migraine

D. Pietrobon

Biomedical Sciences, University of Padova and CNR Institute of Neuroscience, Padova, Italy

It is generally recognized that the primary cause of migraine lies in the brain and that cortical spreading depression (CSD) is the neurophysiological correlate of migraine aura. In animal studies, a single CSD can lead to prolonged activation of meningeal nociceptors and central trigeminovascular neurons, suggesting that CSD may also initiate the headache mechanisms. Gain-of-function mutations in the CaV2.1 (P/Q-type) calcium channel and loss-of-function mutations in the alpha2 Na/K-ATPase cause a rare subtype of migraine with aura: familial hemiplegic migraine (FHM1 and FHM2, respectively). Cav2.1 channels are located in presynaptic terminals and somatodendritic membranes throughout the brain and play a prominent role in initiating action potential-evoked neurotransmitter release at central nervous system synapses. The alpha2 Na/K ATPase is expressed primarily in neurons during embryonic development and at time of birth but almost exclusively in astrocytes in the adult brain. Knockin (KI) mouse models carrying FHM1 or FHM2 mutations show a lower threshold for CSD induction and a higher velocity of CSD propagation. In this lecture I summarize our studies in FHM1 KI mice that reveal the functional consequences of FHM1 mutations on i) the neuronal Ca current in different cortical and trigeminal ganglion (TG) neurons, ii) the unitary synaptic transmission and short-term synaptic plasticity at the main synapses of the cortical microcircuit involving pyramidal cells, fast spiking interneurons and somatostatin-expressing interneurons, iii) the balance between the total excitatory and inhibitory synaptic drive in individual cortical neurons during spontaneous cortical network activity, and iv) CGRP release in the TG and dura. The insights into the pathophysiology of migraine obtained from these studies will be discussed. In general, our data strengthen the view of CSD as a key migraine trigger and point to episodic disruption of the excitatory-inhibitory balance and neuronal hyperactivity as the basis for vulnerability to CSD ignition in migraine.

D.P. is supported by grants from University of Padova (Strategic Project: Physiopathology of Signaling in Neuronal Tissue), Fondazione Cariparo (Excellence Project: Calcium Signaling in Health and Disease) MIUR (PRIN 2010JFYFY2_005) and acknowledges the support from Telethon-Italy (GGP06234).

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L6

Brown adipose tissue: the mammalian prerogative

B. Cannon

Stockholm University, Stockholm, Sweden

During most of the eons when life has existed on earth, living organisms have been controlled in their activity not by their own needs but rather by the environment, in the simple way that life is based on chemical reactions; thus, with decreasing temperatures, activity decreases. The evolutionary advantages of a system that allows organisms to maintain a high and constant body temperature and thus to control their activity in accordance with their own demands is obvious, and different advanced species have attempted to approach this state.
A major breakthrough occurred when development of the true mammals started. In an evolutionarily extremely rapid process, an existing mitochondrial transporter – with an unknown function – was completely changed so that it gained the ability, in a controlled manner, to allow for (the equivalent) of proton transport over the mitochondrial membrane. This allows for the release of the energy accrued by mitochondrial oxidation in the form of heat, instead of transferring it into ATP. Apparently, this development opposes the general concept of life as a system to conserve energy rather than utilize it, but this trans-

formation of a proto-UCP1 to the mammalian UCP1 (uncoupling protein) provided the developing mammals with a totally new mechanism for gaining extra heat: that of nonshivering thermogenesis. We can only imagine that the intention to maintain a high and stable body temperature developed first and that initially the necessary extra heat could only be obtained through shivering, but those (pre)mammals that developed nonshivering thermogenesis obtained the ability to produce the extra heat in a comfortable way, that allowed them to do other things while heat was being produced imperceptibly in their bodies. In our opinion, no other mechanism for nonshivering thermogenesis exists in mammals except for that derived from the activity of UCP1 residing in the dedicated brown adipose tissue – and, to some extent, in certain nominally white adipose tissue depots (brite or beige adipose tissues).

Possession of nonshivering thermogenesis allowed mammals to inhabit niches which were earlier closed for active life: the cold nights, the cold areas of the world, and thus gave them evolutionary advantages. Additionally, brown adipose tissue may have bestowed upon mammals the ability to perform so-called facultative diet-induced thermogenesis, a process in which some of the energy of the food eaten is combusted in an apparently meaningless way, but the process may allow mammals to extract important nutrients from rather low-quality food.

As members of the mammalian group, we as humans share the ability to produce heat through brown adipose tissue activity. Until recently, this ability was thought to be restricted to newborn babies, but the present opinion is that brown adipose tissue is found and is active (when necessary) in a majority of adult humans as well. Thus, it may be said that the development of brown adipose tissue was what gave the developing mammals their evolutionary advantage, and that we still today as humans, even adults, are beneficiaries of this mammalian prerogative of possessing brown adipose tissue.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L7

Teaching and research in physiology in Sub Saharan Africa – achievements and challenges

O. Sofola

Physiology, College of Medicine, University of Lagos, Nigeria, Lagos, Nigeria

Sub Saharan Africa (SSA) is the land mass extending below the Sahara desert excluding countries in the North of Africa and Sudan, according to the World Bank. There are about 52 countries with a population of about 874 million.

The history of teaching of physiology in many medical schools is fairly recent, the earliest possibly in the University of Cape Town (Republic of South Africa – RSA)in 1912, Pretoria (RSA) in 1943, Makerere (Uganda) in 1924, University College Ibadan,(Nigeria) in 1948, and Zimbabwe in 1952. There are about 74 Medical Schools in SSA (1), 26 in Nigeria and 8 in the Republic of South Africa. Teaching of physiology has traditionally been domiciled in Medical schools with majority using the traditional face-to-face method due largely to limited resources. One notable exception is the republic of South Africa, which we call 'European country located in Africa'. Teaching largely utilizes the white board and overhead/multimedia projectors. Many schools are beginning to incorporate some ICT components for teaching. However, we can claim some achievements as several physiologists have been trained in SSA. In addition, we have contributed to the training of several doctors as well as record modest achievements in training of PhDs. South Africa however has staff that is world class. Most universities in sub Saharan Africa depend virtually on government for funding. It is only recently that some universities started charging high tuition fees (2).

Other issues related to teaching challenges include:

- Limited number of PhD holders and low wages.
- Low lecturer : student ratio
- Outdated textbooks
- Limited ICT/ Internet facilities
- Outdated curricula

As for Research, with the exception of South Africa, the research output from the region is very low. It is estimated that SSA contributes less than 0.9% to published work with over 50% from South Africa (3). An analysis of university rankings bears this out as the highest ranked university from SSA is University of Cape Town at 133 (4). Only 5 African universities are in the world's top 1,000. The obvious reason is poor funding and thus less resource for acquiring top equipment for research. This is reflected in the low quality of articles in some regional journals that publish papers with little or no cellular or sub-cellular mechanisms. On the other hand publications from South Africa are top class. However, efforts are being made to play 'catch up'. For example, our laboratory has studied the effects of high salt diet on vascular mechanisms, using rat aortic rings. Our results were confirmed using the pressurized mesenteric artery preparation (5) during the author's tenure as British Heart Foundation Fellow at Leeds University. However, on return to Nigeria, such facility was not available but we are still publishing using the ring preparation (6). Subsequent studies have been on investigating the role of the Epithelial Sodium Channel (ENaC) in hypertensive Nigerians (Dr Elias, PhD thesis, Lagos, 2012) while collaborating with foreign laboratories for DNA sequencing and identification of genetic polymorphisms. We hope that this foray will open new grounds and attract more graduate students to genetic and molecular aspects of physiology.

Other challenges relating to research include:

- Heavy teaching load.
- Low PhD production in addition to in-breeding and inadequate mentoring
- Outdated equipment and little availability of reagents and consumables
- Lack of or limited access to journals
- Brain drain from SSA (3).

This brings up the point of how we in SSA (except perhaps South Africa) can leverage on the superb research facilities in the developed countries. It will also involve the exposure of our staff to research at cellular and sub-cellular levels including cell signaling etc, in line with current trends.

Thus, an appeal is being made to the IUPS to come to the aid of SSA. As the way forward, some suggestions are;

- Provision of sabbaticals for nationals of SSA to laboratories in the developed countries.
- Provision of laboratory space for research training and skills acquisition by our younger colleagues to increase their research capabilities
- A mechanism for equipment transfer through donation of 'surplus to requirement' but useful equipment to universities in SSA. For example, establishing a ' warehouse' system in the IUPS etc for donation of equipment and transfer of such to interested laboratories in SSA.

The thematic of these and other suggestions is assistance to SSA physiologists to boost teaching and research capabilities

and thereby improve on the present dismal situation. This is to arrest the brain drain and make competent and willing researchers to remain in their country and contribute meaningfully to global scientific enterprise.

L8

The Rhythms of Life – What your body clock means to you from eye disease to jet lag

R.G. Foster

University of Oxford, Oxford, UK

We all have embedded within our biology a body clock or "circadian system". The circadian system is used to anticipate the 24 hour day/night cycle so that physiology and behavior can be fine-tuned and adapted to the varying demands of activity and rest. In anticipation of wake, while we are still asleep, body temperature, metabolism and alertness begin to rise in preparation for the activity ahead. And in the same way, in anticipation of sleep, the body begins to slow-down, blood pressure drops, alertness falls and core body temperature declines. The internal clock driving these daily rhythms is not exactly 24 hours, in most of us it is a little longer. As a result, to keep the entire circadian system synchronized, the body clock is adjusted on a daily basis by the changes in light intensity around dawn and dusk. Without this daily re-setting of the clock, 24 hour body rhythms of sleep and wake would rapidly become desynchronized with the real world and lose their adaptive value.

The master clock is located within the base of the brain in a small paired structure called the suprachiasmatic nuclei – abbreviated to the SCN. The SCN are located just above where the optic nerves enter the brain and they contain around 50,000 cells, all of which contain their own individual molecular clock. The SCN cells work together to generate a near 24 signal throughout the body. Small changes in the genes that generate the molecular clock have been associated with the tendency to be a "morning" or "evening" person. Until recently, It was thought that only the SCN contains clock cells, but we now know that all cells of the body contain their own molecular clock. As a result the SCN coordinates the 24h rhythmic activity of billions and billions of cells throughout the body. The SCN receives a direct projection from the eye which adjusts all the cells in the SCN to the light/dark cycle. In addition to the rod and cone photoreceptors of the eye which provide us with our sense of vision, the eye contains a recently discovered 3rd class of light-sensitive cell called a "photosensitive retinal ganglion cell". There are relatively few of these cells within the eye but they are critical for the measurement of environmental brightness, and hence adjustment of the SCN to dawn and dusk.

In parallel with our increased understanding of the neuroscience of circadian rhythms, there is a growing appreciation of the severe consequences of ignoring the impact of these rhythms on diverse areas our health and quality of life. For example, the discovery of the pRGCs within the eye has transformed our understanding of blindness. We now appreciate that eye diseases which result in rod and cone photoreceptor death need not result in the loss of pRGC light detection. In these cases if a visually blind individual retains pRGC function they should be encouraged to expose their eyes to sufficient day-time light to maintain normal circadian regulation and sleep-wake timing. Even without sight, these eyes should be preserved at all costs as their loss will plunge an individual into a world without any sense of time; Additionally, individuals with eye diseases of the inner retina, which result in retinal ganglion cell death (e.g. glaucoma), are at particular risk of circadian rhythm disruption. Such individuals would be strong candidates for treatment with appropriately timed medications that help consolidate sleep timing. Until recently, sleep and circadian rhythms have rarely been addressed in clinical departments of ophthalmology, yet worldwide there are over 50 million people classified as blind and perhaps a further 300 million with severe visual loss. The quality of life and health of many of these individuals would be improved if there were a greater understanding by ophthalmologists of how the eye regulates our internal time.

Jet-lag represents another example where the circadian system becomes uncoupled from the environment, but in this case because of travel across multiple time-zones. Upon exposure to the new light/dark cycle it takes the circadian system days to readjust to local time. Furthermore, the timing of the multiple cellular clocks throughout the body becomes uncoupled for variable periods of time before adjustment. The net result is a body that is poorly adapted to function in the new time-zone. Insomnia, fatigue, impaired cognition, depression, metabolic and gastrointestinal problems all persist until the circadian system has adapted fully to the new light/dark cycle. The number of people affected by jet-lag is rising rapidly, but little is done to address the problems suffered by these individuals.

This presentation will consider the remarkable discoveries of how our circadian rhythms are generated and regulated by light. The second part of the talk will consider how a knowledge of this physiology is having a major impact upon both medicine and in the way we structure and our society.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L9

Calcium signal mechanisms in secretory cells: physiology and pathology

O.H. Petersen

Biosciences, Cardiff University, Cardiff, UK

More than forty years ago, I showed that acetylcholine (ACh) evokes fast release of Ca^{2+} from intracellular stores in exocrine glands, delayed influx of Ca^{2+} from the extracellular solution and activation of Ca^{2+} extrusion (Nielsen & Petersen 1972). The now established basic elements of cellular Ca^{2+} homeostasis in electrically non-excitable cells, namely messenger-mediated opening of Ca^{2+} channels in intracellular stores, store-

operated Ca^{2+} entry and Ca^{2+} pump – mediated extrusion of Ca^{2+} into the extracellular solution (Petersen & Tepikin 2008) were thus identified in the 1972 paper (Nielsen & Petersen 1972). The first measurements of the cytosolic Ca^{2+} concentration ($[Ca^{2+}]i$) in exocrine gland cells were performed using the Ca^{2+}-activated K+ channel as an intrinsic Ca^{2+} sensor. Combining results of single-channel current recordings in excised inside-out membrane patches, at different well-defined Ca^{2+} concentrations in solutions in contact with the membrane inside, with cell-attached single channel recordings from intact acinar cells in the resting state, as well as after stimulation, showed that resting $[Ca^{2+}]i$ was between 50 and 100 nM and that stimulation caused a significant rise in this level (Maruyama et al 1983). Later imaging studies, employing fluorescent Ca^{2+}-sensitive dyes and patch clamp electrophysiology, showed that stimulation with physiologically relevant hormone concentrations did not evoke a sustained elevation of $[Ca^{2+}]i$, but repetitive short-lasting spikes and that these were mostly confined to the apical granular part of the pancreatic acinar cells (see Petersen & Tepikin 2008). These local Ca^{2+} transients stimulated the exocytotic secretion process of digestive enzymes. Indeed every single Ca^{2+} transient evokes a transient exocytotic response (Petersen & Tepikin 2008). The continued generation of repetitive local Ca^{2+} signals, evoked by continuous stimulation with a physiological hormone level, relies on the Ca^{2+} tunnel function of the endoplasmic reticulum, the concentration of Ca^{2+} release channels in the apical granular area and the peri-granular mitochondrial belt, functioning as a Ca^{2+} firewall (see Petersen & Tepikin 2008). A sustained elevation of $[Ca^{2+}]i$ in the pancreatic acinar cells, evoked by hyperstimulation, only causes an initial transient secretory response but then, in contrast to what happens with physiological stimulation, activates intracellular proteases. This protease activation is initiated in the apical granular area and at the same time transformation of the normally electron-dense zymogen granules into empty looking vacuoles begins. Both intracellular protease activation and vacuolization can be prevented by intracellular Ca^{2+} chelation (Raraty et al 2000). These processes are characteristic of what happens in the human disease acute pancreatitis, which is mostly caused by alcohol abuse or gallstone complications. Surprisingly, we found that ethanol – even at extraordinarily high and unrealistic concentrations – had very little effect on Ca^{2+} homeostasis in intact pancreatic acinar cells, whereas fatty acid ethyl esters (FAEEs) – non-oxidative products of ethanol and long chain fatty acids – are very effective releasers of stored Ca^{2+} in pathophysiologically relevant concentrations (Gerasimenko et al 2009,2011). The surprisingly weak effect of ethanol itself is due to an intrinsic protective effect of calmodulin (CaM). In permeabilized acinar cells, ethanol – even at a modest concentration – did evoke significant Ca^{2+} release from internal stores, as well as trypsinogen activation, but these effects could be markedly suppressed by adding CaM to the external solution, which in these experiments was in direct contact with the cytosol (Gerasimenko et al 2011). Remarkably, a Ca^{2+}-like peptide (CALP-3) completely suppressed trypsinogen activation induced even by a very high ethanol concentration (Gerasimenko et al 2011). Since the Ca^{2+} releasing effect of FAEEs is much stronger than that of ethanol alone, the mechanism of action has been explored in some detail. Knock-out of IP3 receptors of types 2 and 3 markedly reduced both the Ca^{2+} release and the trypsinogen activation induced by FAEEs to very low levels, indicating that most of the Ca^{2+} release occurs through the very same receptors that also serve normal stimulus-secretion coupling (Gerasimenko et al 2009). Under physiological conditions the IP3 receptor activation is moderate, whereas under pathological conditions maximal opening of these channels occurs, with the result that the stores are completely emptied. Overall, our results indicate that even a small, but sustained, rise in $[Ca^{2+}]i$, while not in itself necessarily causing damage, sensitizes cells to noxious stimuli, for example oxidative stress, markedly increasing the risk for necrosis (Ferdek et al 2012).

Stem cell biology for vascular medicine

T. Asahara

Tokai University, Isehara, Kanagawa, Japan

The finding that Endothelial progenitor cells (EPCs) can home to sites of neovascularization and differentiate into endothelial cells in situ is consistent with “vasculogenesis”, a critical paradigm well described for embryonic neovascularization, but recently also proposed for the adult organism in which a reservoir of progenitor cells contributes to post-natal neovascular formation. The discovery of EPCs has therefore drastically changed our understanding of adult blood vessel formation. Furthermore, people noticed the valuable capability to translate EPC potential to improve the clinical applicability in the fight against cardiovascular diseases. Many groups involved in clinical trials have demonstrated that EPC therapy is safe and feasible for the treatment of critical limb ischemia and cardiovascular diseases. However, many issues in the field of EPC biology, especially in regards to the proper and unambiguous molecular characterization of these cells still remain unresolved, hampering not only basic research but also the effective therapeutic use and widespread application of these cells.

In this presentation, I introduce the recent concept of EPC identification in terms of hematopoietic and non-hematopoietic

EPCs along with the development of EPC biology research. Furthermore, I define the role of circulating EPCs in post-natal neovascularization to illustrate the future direction of EPC therapeutic applications.
I overview candidate cells for cardio- and peripheral- vascular diseases, introduce the practical example of therapeutic application of cells to ischemic disease patients and discuss the future direction.

L11

Local protein synthesis

E. Schuman

c/o MPI Biophysics, Max Planck Institute for Brain Research, Frankfurt, Germany

An individual neuron in the brain possesses approximately 10,000 synapses, many of which are hundreds of microns away from the cell body, which can process independent streams of information. During synaptic transmission and plasticity, remodeling of the local proteome occurs via the regulated synthesis of new proteins. I will discuss previous and current studies aimed at understanding how the local transcriptome, obtained with deep sequencing, and the local proteome might influence synaptic transmission and plasticity.

Vascular metabolism: principles and strategies

P. Carmeliet

Laboratory of Angiogenesis and Neurovascular link, Vesalius Research Center, VIB - KU Leuven, Leuven, 3000 Leuven, Belgium

Angiogenesis, the growth of new blood vessels, plays a crucial role in numerous diseases, including cancer. Anti-angiogenesis therapies have been developed to deprive the tumor of nutrients. Clinically approved anti-angiogenic drugs offered prolonged survival to numerous cancer patients. However, the success of antiangiogenic VEGF-targeted therapy is limited in certain cases by intrinsic refractoriness and acquired resistance. New strategies are needed to block tumor angiogenesis via alternative mechanisms. We are therefore exploring whether targeting endothelial metabolism can be a possible alternative therapeutic strategy for anti-angiogenic therapy.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L13

Gastrointestinal hormones and the dialogue between gut and brain

G. Dockray

Cell and Molecular Physiology, University of Liverpool, Liverpool, UK

The landmark discovery by Bayliss and Starling in 1902 of the first hormone, secretin, was based in part on the observation that a response (pancreatic secretion) following a stimulus (intestinal acidification) occurred after section of the relevant afferent nerve pathway. With the subsequent discovery of many more hormones, numerous examples of interactions between endocrine and autonomic efferent pathways emerged. But it was to be nearly 80 years before it was discovered that visceral afferent neurons could themselves also be targets for gut and other hormones. Signalling from gut to brain by gut hormones acting on vagal afferent neurons is now recognised to be an early step in the activation of vagovagal reflexes regulating gastric acid secretion and in controlling nutrient delivery to the intestine by modulating gastric emptying. Importantly, gut hormones acting on vagal afferent neurons also influence food intake and interest in these mechanisms has grown rapidly in view of the alarming global increase in obesity. Several of the gut hormones released by nutrients (cholecystokinin, CCK; PYY3-36; glucagon-like peptide-1, GLP-1) excite vagal afferent neurons to activate an ascending pathway via the brainstem and hypothalamus leading to inhibition of food intake. Conversely others eg ghrelin, that are released in the inter-digestive period, inhibit vagal

afferent neurons leading to increased food intake. Moreover, the vagal afferent neurons targeted by gut hormones are now emerging as integrators of several different types of peripheral signal. Thus, (a) leptin stimulates these neurons and potentiates the effects of CCK indicating mechanisms that integrate adipose- and gut-derived signals. (b) Nutrient status determines the neurochemical phenotype of vagal afferent neurons and in particular regulates a switch between states that emphasise orexigenic or anorexigenic signalling; for example food withdrawal increases the expression of receptors (eg cannabinoid, CB1, receptor) and a putative neuropeptide transmitter (melanin concentrating hormone, MCH) that are associated with stimulation of food intake, while refeeding increases the expression of a receptor (Y2) and neuropeptide transmitter (cocaine and amphetamine regulated transcript, CART) associated with satiety signalling. (c) The gut luminal and tissue environments modulate vagal sensitivity to gut hormones through mechanisms that vary with different regions of the gut. Thus small intestinal infection, and proinflammatory cytokines, potentiate vagal afferent responses to CCK leading to loss of appetite; in the stomach, however, infection and inflammation can be regarded as physiological states, and here expression of plasminogen activator inhibitor (PAI)-1 is increased by inflammation and depresses vagal afferent sensitivity to CCK, thereby protecting nutrient intake. Finally, (d) shifts in the gut microbiota that occur in obesity are associated with leptin insensitivity in vagal afferent neurons, and therefore insensitivity to CCK as well, which appears to develop before leptin-insensitivity in hypothalamic neurons. Together these observations indicate a hitherto unsuspected level of sophistication in the signalling between gut to brain that underlies homeostatic mechanisms controlling nutrient intake. They also suggest new opportunities to develop treatments for obesity and feeding disorders.

L15

Physiological insights into the developmental origins of non-communicable disease

M. Hanson

Human Development and Health, University of Southampton, Southampton, UK

Non-communicable diseases (NCD) including cardiovascular disease, diabetes, chronic lung disease and some forms of cancer now pose an increasing threat to global health and the economies of both developed and developing countries, where they are now overtaking communicable diseases (1). Not simply diseases of affluence, attempts to reduce their incidence through adult lifestlye are not succeeding (2). Risk of such disease is set in part during early life, when environmental influences including mother's diet, body composition and exposure to stress, affect the development of her fetus and newborn, establishing its responses to later environmental challenges such as an obesogenic lifestyle. Paternal lifestyle can also produce developmental effects via the sperm. Such parental effects may confer fitness advantage by enabling rapid phenotypic response to an environmental change (3). If the cues which the developing embryo and fetus detect are inaccurate, e.g. unbalanced maternal diet or because nutritional transition occurs between generations through migration or rapid economic improvement, offspring's responses are mismatched to later environmental challenges, leading to greater risk of NCD. Whilst undernutrition remains an enormous problem throughout the developing world, in both developing and developed societies adverse consequences of over- and undernutrition co-exist (4). The resulting risk can be transmitted down multiple generations. The consequences affect many aspects of the lifecourse including reproductive health, behavioural, cognitive problems, osteoporosis, sarcopenia and some allergic conditions. Epidemiological, human clinical and basic science research has now indicated underlying mechanisms, many of which involve epigenetic processes (5, 6). These can thus serve as early markers of later risk and they are in principle reversible by dietary, endocrine or pharmacological means. They include DNA methylation, but also changes in histone protein structure and small non-coding RNAs. New evidence is revealing how such processes, which extend beyond imprinted genes, can modify the effects of transcription factors on gene expression and thus responses to later challenges (7). The specific patterns of CpGs methylated can be important, and the regions of importance are not solely in CpG-rich islands. These physiological insights indicate the opportunity for complex social interventions before conception to reduce NCD risk in the next generation.

Mitochondrial superoxide flashes

H. Cheng and X. Wang

State Key Laboratory of Biomembrane and Membrane Biotechnology, Peking University, Beijing, China

Respiratory mitochondria spontaneously undergo quantal, brief bursts of superoxide production, named "superoxide flashes". A property common to all species and cell types examined, generation of superoxide flashes is coupled to transient opening of mitochondrial membrane permeability transition pore (mPTP) and depends on the functional integrity of electron transfer chain (ETC). Unitary properties of superoxide flashes (amplitude, duration) appear to be stereotypical, at levels from isolated mitochondria to whole organs (e.g. beating heart) and even to live animals. Functionally, superoxide flashes act as elemental reactive oxygen species (ROS) signaling events ("signaling ROS") that participate in diverse cellu-

lar processes, whereas constitutive electron leakage from the ETC to molecular oxygen produces the bulk of ROS for the regulation of redox homeostasis ("homeostatic ROS"). In particular, superoxide flash incidence provides a digital readout to gauge the glucose- and insulin-stimulated mitochondrial metabolism in live animals, and a novel biomarker of the oxidative stress in hyperosmotic stress and ischemia-reperfusion injury. These findings support the notion that ROS act as second messengers in physiological and pathophysiological contexts, and demonstrated the paramount importance of spatiotemporal organization of ROS signals in determining their signaling efficiency and modality.

T-type calcium channels, thalamic firing modes, and control of consciousness and cognition

H. Shin

Center for Cognition and Sociality, Institute for Basic Science, Daejeon, Republic of Korea

The thalamocortical circuit has long been considered important in control of consciousness. Series of works utilizing mice with genetic modifications of the alpha1G T-type Ca2+ channel have helped to settle the long held issue on the critical role, in vivo, of T-type channels in control of neuronal firing mode and consciousness. These have been shown by studies on absence epilepsy, sleep, and alcohol-induced loss of consciousness. As we explore further into the structure and function of the thalamocortical circuit, especially in relation to other brain regions, we begin to find that the thalamus has critical roles in other fundamental brain functions, i.e. in cognition and emotion control. Thus, we showed that the thalamus is deeply involved in control of empathy fear by the anterior cingulate cortex and in extinction of fear memory by the amygdala and prefrontal cortex. In the latter case, we began our studies with a mutant mouse for the phospholipase Cbeta4 gene, a signaling molecule downstream to mGluR1. Using gene manipulation, pharmacology, lesion, single-unit recording via tetrodes, and intracranial electrical stimulations, we found that the mediodorsal thalamus plays a critical switch function in extinction of fear memory through two different firing patterns, burst vs tonic. The demonstration of the opposite functions, suppression vs enhancement, of the two firing modes on extinction of fear memory clearly shows the distinctive physiological roles of the two firing modes of the thalamus in control of cognition, in addition to their roles in control of consciousness. Current studies on this issue will be discussed.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L18

Role of ATP-regulated potassium channels in pancreatic alpha- and beta-cells

P. Rorsman

Radcliffe Department of Medicine, University of Oxford, Oxford, UK

Insulin and glucagon are the body's principal gluco-regulatory hormones. They are secreted by the pancreatic β- and α-cells in response to hyperglycaemia and hypoglycaemia, respectively. The metabolic regulation of insulin secretion is well understood: glucose-induced closure of ATP-sensitive potassium channels (KATP-channels), which are spontaneously active at low glucose, results in membrane depolarization, initiation of Ca2+-dependent electrical activity and stimulation of insulin granule exocytosis. An increase in plasma glucose leads to inhibition of glucagon secretion. Surprisingly, glucagon-secreting α-cells are equipped with KATP-channels of exactly the same molecular composition as those found in the β-cells. The role of the KATP-channels in α-cells remains enigmatic. How can closure of KATP-channels result in stimulation of insulin secretion from β-cells but inhibition of glucagon secretion from the α-cells?
Our recent studies on α-cells in freshly isolated intact islets have established that the KATP-channels are active in α-cells exposed to 1mM glucose (a condition associated with stimulation of glucagon secretion) and that they close when glucose is increased to 6mM. This results in ~10mV membrane depolarization and <2-fold increase in action potential frequency. Yet, glucagon secretion measured in parallel from the same batch of pancreatic islets was inhibited by ~50%. The KATP-channel blocker tolbutamide mimicked the effects of glucose on electrical activity and glucagon secretion. Importantly, the depolarizing effect of glucose or tolbutamide was associated with a 10-15mV reduction of action potential peak voltage. The sodium channel blocker TTX and the P/Q-type calcium channel inhibitor agatoxin mimicked the effects of glucose on glucagon secretion/electrical activity. These data suggest that KATP-channel closure exert dual effects on secretion/electrical excitability depending on the complements of voltage-gated ion channels. In cells in which action potential firing depends on ion channels that do not undergo much voltage-dependent inactivation (as exemplified by the β-cell), membrane depolarization will stimulate secretion. In cells in which action potential firing instead involves ion channels that exhibit voltage-dependent inactivation (like the α-cell), membrane depolarization, via reduced action potential height and less activation of P/Q-type calcium channels, results in inhibition rather than stimulation of secretion.
These data may help to explain why glucagon secretion is increased in diabetic patients (exacerbating the hyperglycemia due to the lack of insulin). Potential therapeutic implications of these findings will be discussed.

Sifting circuits for motor control

T.M. Jessell

HHMI, Kavli Institute for Brain Science, Depts. Neuroscience, Biochemistry and Molecular Biophysics, Columbia University, New York, NY, USA

This talk will examine two aspects of the organization of spinal circuits devoted to the control of limb movement – the logic of circuit assembly, and the link between circuit wiring and motor behavior. The application of molecular genetic methods to problems of neuronal diversity and connectivity has begun to emphasize the importance of neuronal settling position as an adjunct to cell recognition in driving the assembly of motor microcircuits. Through this analysis it has become evident that the detailed wiring of local motor circuits differs systematically, as a function of limb muscle position and the biomechanical demands of individual joints. Molecular appreciation of the vast diversity of spinal motor neuron and interneuron subtypes has also permitted more precise ways of perturbing, genetically, the function of individual spinal neuronal subsets and examining the consequences of such manipulations for motor behavior. Examples of the way in which this general approach can be applied to questions of local inhibitory control, and the internal representation of motor output, will be discussed.

Structure and function of voltage-gated sodium channels at atomic resolution

W.A. Catterall

Pharmacology, University of Washington, Seattle, WA, USA

Voltage-gated Na+ channels initiate action potentials in excitable cells and are important targets for drugs. Recent research gives new insight into the structural basis for permeation, drug-block, and voltage-dependent gating. Voltage-sensing depends on the S4 segments, which move outward through a gating pore via a 'sliding-helix' mechanism. Outward movement of S4 is coupled to pore-opening by tilting and rotation of the S6 segments. A structural model reveals conformational changes underlying activation and pore-opening, and disulfide locking of substituted cysteines demonstrates voltage-dependent formation of ion pairs during channel activation, as in the sliding-helix model. Sodium channel blocking drugs bind to a conserved receptor site in the inner pore, and binding is enhanced by repetitive opening of the pore and inactivation of the channel. A three-dimensional view of these structural components is provided by a high-resolution structure of a voltage-gated Na+ channel from Arcobacter butzleri (NavAb) captured in a closed-pore conformation with four activated voltage-sensors at 2.7 Å resolution. The arginine gating charges make multiple hydrophilic interactions within the voltage-sensor, including unanticipated hydrogen bonds to the protein backbone. Comparisons to previous open-pore Kv channel structures suggest that the voltage-sensor domains and the S4-S5 linkers dilate the central pore by pivoting around a hinge at the base of the pore. The NavAb selectivity filter is short, ~4.6 Å wide, and water-filled, with four acidic glutamate side-chains surrounding the narrowest part of the ion-conduction pathway. This unique structure presents a high-field-strength anionic coordination site, which confers Na+ selectivity through partial dehydration via direct interaction with glutamate side-chains. Multiple sodium binding sites are observed in crystals and in molecular dynamics simulations, supporting a 'knock-on' model of permeation. The local anesthetic site is located in the central cavity of the pore. Fenestrations in the sides of the pore are unexpectedly penetrated by fatty-acyl chains that extend into the central cavity, and these portals are large enough for entry of small, hydrophobic pore-blocking drugs. Determination of the crystal structure of NavAb in two similar inactivated states suggests asymmetric pore collapse as the mechanism of slow inactivation of NavAb channels and reveals dramatic conformational change in its drug receptor site that might underlie preferential voltage-dependent block of inactivated sodium channels.

New insights in the fetal origins of adult cardiometabolic disease

S. Davidge, C. Rueda-Clausen, J. Morton, V. Dolinsky and J. Dyck

Women and Children's Health Research Institute, University of Alberta, Edmonton, AB, Canada

Cardiovascular disease causes the greatest mortality in the world today. It is now recognized that the quality of the fetal environment during early development is important for cardiovascular health in later life. Understanding the consequences of a poor *in utero* environment leading to cardiometabolic disease creates an exciting window of opportunity to diagnose, intervene and ultimately reduce the development of cardiovascular disease.

Fetal hypoxia is one of the most common consequences of complicated pregnancies worldwide. Intrauterine hypoxia is associated with a variety of maternal, placental and fetal conditions, such as chronic maternal pulmonary disease, heart disease, acute respiratory infections, preeclampsia as well as placental insufficiency and hypoxic environments. Our studies use a model of chronic maternal hypoxia (rats housed at 11.5% oxygen for their last third of pregnancy) that leads to intrauterine growth restriction (referred to here as IUGR).

For our vascular studies, we hypothesized that exposure to prenatal hypoxia would cause changes in vascular function that would impair vasodilation later in life in an age- or sex-dependent manner. We found that flow-induced vasodilation was unaffected at a young age (3 months old) but was significantly reduced in aging (12 months) IUGR animals compared to aging controls. Interestingly, nitric oxide (NO)-mediated vasodilation was significantly reduced in both young and aging IUGR males and females (1), suggesting altered pathways of vasodilation in offspring exposed to prenatal hypoxia for both sexes. Overall, our data suggest that a change in the mechanisms of vasodilation occurring at an earlier age in IUGR offspring may predispose them to adult cardiovascular diseases. In regard to cardiac function, we have used *in vivo* echocardiographic techniques that demonstrated that hypoxia-induced IUGR is associated with the development of chronic car-

diopulmonary dysfunction (such as diastolic dysfunction and pulmonary hypertension) in offspring as the age (2). Moreover, cardiac tolerance to ischemia/reperfusion injury is reduced in hypoxic offspring by 4 months of age. Furthermore, we identified a mismatch in glucose metabolism leading to proton accumulation in the postischemic myocardium of offspring born IUGR as a potential mechanism involved (3). We further identified that in only the male offspring, IUGR was associated with an increase in myocardial oxidative stress as evidenced by an increased GSSH/GSH ratio (4).

We further expanded our studies to address the impact of prenatal hypoxia on indices of metabolic syndrome. In IUGR offspring fed a high fat (HF)-diet, there was a relative increase in intra-abdominal fat deposition and size, as well as an increase in fasting plasma concentrations of leptin, triglyceride and free fatty acids by 3 months of age that was not evident in the control group. These changes were accompanied by *in vivo* insulin resistance and impaired glucose tolerance (5). Interestingly, we showed a synergistic effect of prenatal hypoxia and postnatal high fat diet to reduce the capacity for recovery from cardiac ischemia/reperfusion injury (6). Thus offspring exposed to prenatal hypoxia do not appear to have reserve against secondary insults such as high fat diet or aging. We next addressed a potential intervention strategy. Since resveratrol (Resv), the polyphenol produced by plants, exerts insulin-sensitizing effects, we tested whether Resv could prevent deleterious metabolic effects of being born IUGR. We showed that in only the IUGR offspring, feeding a HF diet supplemented with Resv for 9 weeks, from the time of weaning, prevented intra-abdominal fat deposition, improved the plasma lipid profile and ameliorated insulin resistance and glucose intolerance (7). Our results suggest that early, postnatal intervention can alleviate HF-diet induced pathologic metabolic phenotypes in young, adult offspring born from a complicated pregnancy associated with prenatal hypoxia.

Overall, our laboratory has demonstrated that prenatal hypoxia leads to intrauterine growth restriction and impairs later life endothelial-dependent vascular function and decreases cardiac tolerance to ischemia/reperfusion injury. We have also noted that compromised offspring do not have the reserve to accommodate a secondary stress such as consuming a high fat diet. Understanding the impact of different interventions such as Resv will improve our knowledge of mechanisms and address potential strategies for early intervention for children at risk due to their prenatal history.

An overview of Physiome activities

P. Hunter

University of Auckland, Auckland, New Zealand

Multi-scale models of organs and organ systems, based on model encoding standards, are being developed under the umbrella of the IUPS Physiome Project and the Virtual Physiological Human (VPH) project funded by the European Commission. These computational physiology models deal with multiple physical processes (coupled tissue mechanics, electrical activity, fluid flow, etc) and multiple spatial and temporal scales. They are intended both to help understand physiological function and to provide a basis for diagnosing and treating pathologies in a clinical setting. A long term goal of the project is to use computational modeling to analyze integrative biological function in terms of underlying structure and molecular mechanisms. Web-accessible databases, based on the standards, have been established for models and model-related data at the cell, tissue, organ and organ system levels. This talk will discuss recent developments in the IUPS Physiome Project.

Integration and modulation of intercellular signalling underlying blood flow control

S.S. Segal

Med Pharm Physiology, University of Missouri, Columbia, MO, USA and Dalton Cardiovascular Research Center, Columbia, MO, USA

Blood flow control in the microcirculation requires coordinated interplay among the multiple branches of vascular resistance networks. These branches include arterioles embedded within the tissue parenchyma and their upstream feed arteries located external to the tissue. Vasoactive stimuli arising from cellular activity at discrete locations within a tissue (e.g., skeletal muscle fibres of motor units) activate receptors and ion channels of both smooth muscle cells and endothelial cells. The ensuing chemical and electrical signals must be integrated among vessel branches to effectively increase local perfusion in accord with local nutritive requirements of metabolic demand.

Ascending vasodilatation is an intrinsic property of the resistance vasculature that enables signals initiated at discrete sites to spread from cell to cell along and among network branches. As demand (e.g., exercise intensity) increases, dilatation originating in distal arterioles governing capillary perfusion spreads upstream into intermediate and proximal arterioles that control the distribution and magnitude of tissue blood flow. Ascending dilatation of feed arteries coordinately governs total flow entering the microcirculation. The axial orientation of endothelial cells and their robust coupling to each other through gap junctions underscores the effectiveness of the endothelium as a cellular pathway for transmitting signals along vessel walls. In turn, heterocellular coupling through myoendothelial gap junctions enables radial signalling from the endothelium into consecutive smooth muscle cells to coordinate their relaxation and the spread of vasodilatation. Through altering cell-to-cell coupling, the regulation of gap junction expression and patency (e.g., by phosphorylation, nitrosylation and accessory proteins) can modulate both longitudinal and radial signalling in resistance networks. Intercellular signalling is also modulated by ion channels in plasma membranes. For example, the fall in membrane resistance upon activating small- and intermediate- Ca^{2+} activated K^+ channels (SK/IK) along the endothelium promotes the dissipation of electrical signals, thereby "tuning" the effective distance of transmission. Inherent to myoendothelial coupling is that variations in the size, number and functional channels of smooth muscle cells further modulate longitudinal signalling. In addition to their intimate coupling to the endothelium, smooth muscle cells throughout resistance networks are enmeshed by a plexus of perivascular nerves coursing along the adventitia. Upon physical stress, increased sympathetic nerve activity promotes vasoconstriction that competes against vasodilator signals arising from both skeletal muscle and endothelium. In turn, the activation of adrenergic receptors on smooth muscle cells generates second messengers (e.g., inositol trisphosphate and Ca^{2+}) that can diffuse through myoendothelial gap junctions to signal endothelial cells reciprocally. Independent of autacoid production, the opening of SK/IK (i.e., endothelium-dependent hyperpolarization) can thereby modulate vasoconstriction along the network while attenuating the efficacy of electrical conduction. Thus, irrespective of gap junctions, regulating ion channels in plasma membranes can govern local perfusion by modulating ascending vasodilatation. Such dynamic interactions between parenchymal cells, vascular cells and perivascular nerves effectively coordinate vasomotor activity throughout resistance networks to ensure perfusion according to local needs. Vasodilatation predominates in distal and intermediate arterioles, where sympathetic vasoconstriction is overridden as metabolic demand increases (i.e., "functional sympatholysis"). At the same time, resistance is maintained in proximal arterioles and feed arteries, where sympathetic neuroeffector signalling suppresses ascending vasodilatation via complementary actions on both smooth muscle and endothelium. While restricting dilatation of proximal vessels limits maximal tissue perfusion, the negative modulation of ascending vasodilatation maintains peripheral resistance and arterial perfusion pressure. In doing so, the integration of intercellular signalling underlying blood flow control ensures the ability to support the elevated demands of intense physical activity. Ongoing investigations focus on understanding how such key signalling events are altered by aging and disease.

The renin-angiotensin system: new concepts and perspectives

R.A. Santos

Physiology and Biophysics, Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil

It is well known that the renin-angiotensin system (RAS) is a key regulator of the cardiovascular system and the hydro-electrolyte balance. The classical concept of the RAS in which the octapeptide angiotensin II was the only biologically active end product has undergone important changes In the past years. The biological actions of this system are now considered to be performed by two main axes: ACE/Ang II/AT1R and ACE2/Ang-(1-7)/Mas. Resembling Ang II, Ang-(1-7) has pleiotropic actions in the body. However, in many instances the effectors of these two arms produce opposite effects. One of the most remarkable differences between Ang II and Ang-(1-7) is their opposite effect in blood vessels: Ang II is a potent vasoconstrictor while Ang-(1-7) is vasodilator. In the brain both peptides modulates the autonomic system activity producing similar effects in some regions (rostro-ventrolateral medulla for example) and opposite effects in others. Central administration of Ang-(1-7) increases the baroreflex control of arterial pressure while Ang II produces an opposite effect. Ang-(1-7) is importantly involved in cardiac function (inotropism, rhythmicity), modulation of regional vascular resistance and endothelial function, favoring the production of NO. It appears to be a key player in reproduction, acting both on ovarian and testicular function. Ang-(1-7) also influences glucose and lipid homeostasis. One of the most prominent actions of Ang-(1-7) is its anti-fibrotic effect which was demonstrated in the heart, lungs, liver, kidney and tumors. The widespread physiological influence of Ang-(1-7) in many organs and systems appears to be dependent of its stimulatory effect on AKT activity which plays a central role in molecular signaling. However, recent phosphoproteomic data indicate that in parallel to the Ca+2-independent activation of the PI3K/AKT pathway, Ang-(1-7) activates potent intra-cellular anti-proliferative pathways which may explain its anti-angiogenic/anti-tumoral activity. Recently studies have addressed the therapeutic potential of the ACE2/Ang-(1-7)/Mas axis. The results obtained with Mas stimulation or ACE2 activation in conditions such as myocardial infarction, hypertension, trombogenesis, heart fibrosis and stroke suggest that the relevance of angiotensin-(1-7) could go beyond its role in physiology. Recently we have identified a novel component of the RAS, the heptapeptide alamandine, which can be formed from angiotensin A by ACE2 and from Ang-(1-7) by decarboxilation of the aspartate residue . Alamandine produces effects resembling those of Ang-(1-7), including vasodilation and central cardiovascular effects at the

ventro-lateral medulla. However, differently from Ang-(1-7) it acts independent of Mas. Alamandine binds to the Mas-related protein G-Protein receptor, MrgD. These novel findings expanded our understanding of the RAS and opens new perspectives for further exploring its physiological significance and therapeutic possibilities.

TRPV1 channels: from molecules to physiology

T. Rosenbaum

Neurodevelopment and Physiology, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México, Mexico, Mexico

Transient receptor potential (TRP) channels were first described in Drosophila, where photoreceptors carrying trp gene mutations exhibited a transient voltage response to continuous light (Cosens and Manning, 1969). Since that time the TRP channel family has grown to include at least 20 members. TRP channels exhibit a wide variety of functions: invertebrate phototransduction, responses to painful stimuli and to moderate temperature changes, regulation of intracellular calcium stores, receptor mediated excitation and modulation of the cell cycle. Despite the clear physiological importance of TRP channels, little is known about what regulates their function or about their structure.

One type of TRP channel, TRPV1, is a polymodal receptor that integrates a number of painful stimuli. These stimuli include: noxious heat,,extracellular acidification, with a pKa of about 5.3, anandamide and other arachidonic acid metabolites and capsaicin, a pungent extract from plants in the Capsicum family (Rosenbaum and Simon, 2007). A combination of electrophysiological, molecular biology and biochemical techniques has allowed us to study the structural and functional properties of the TRPV1 channel and we have determined important regions for its function. For example, by constructing several TRPV1- channel mutants in which cysteine residues were substituted for other amino acids and by using cysteine-modifying compounds, we have found a single cysteine residue located at the second ankyrin repeat of the N-terminus (C157) of TRPV1, which is solely responsible for activation of this channel by allicin, a pungent compound found in plants such as onions and garlic (Salazar et al., 2008).

We have also engineered a functional cysteineless-TRPV1 in which all 18 native cysteines were substituted for other amino acids and used it to perform experiments with cysteine-modifiers. These experiments have allowed us to locate the gate that controls ion fluxes through the TRPV1 channel to an intracellular region in the S6 transmembrane domain near residue Y671 as well as to identify a constriction in the pore (near residue L681), which impedes the passage of larger molecules to the pore (Salazar et al., 2009).

More recently, we have identified a new endogenous bioactive lipid that functions as a direct agonist of TRPV1, lysophosphatidic acid, and we have shown that this lisyolipid binds to residue K710 in the proximal C-terminus of TRPV1 that results in an increase of the open probability of the channel (Nieto-Posadas et al., 2012).

Although the field of TRP-channel study has observed important advances, further studies are still needed to fully comprehend how these proteins are gated.

Purinergic signalling: the discovery and current developments

G. Burnstock

Autonomic Neuroscience Centre, University College London, London, UK

The talk will begin with a description of the discovery in the early 1970's of purinergic neurotransmission (i.e. ATP acting as a neurotransmitter) and the struggle we had for the next 20 years to establish this hypothesis. It is now recognised that the purinergic signalling system is one of the most ancient and widespread intercellular signalling systems in living tissue. The major conceptual steps leading to our current understanding of purinergic signalling will be described, including ATP as a cotransmitter, cloning and characterisation of P1 (adenosine), P2X (ATP) ion channel and P2Y (ATP, ADP, UTP, UDP) G protein-coupled receptors, physiological release of ATP by mechanical deformation of cells, identification of ectonucleotidases and both fast and long-term (trophic) purinergic signalling. Reference will be made to some of the key scientists who have influenced its development. Finally, some of the exciting areas of current interest will be considered, including in particular the pathophysiology of purinergic signalling and its therapeutic potential.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

L27

The molecular mechanisms of signaling at chemical synapses

E. Gouaux

Oregon Health & Science University, Oregon, OR, USA

Rapid signal transduction at chemical synapses involves calcium-dependent neurotransmitter release from presynaptic neurons, binding of transmitter to ligand-gated ion channels located primarily on the postsynaptic membrane, and subsequent uptake of transmitter by way of sodium-coupled neurotransmitter transporters. Chemical synapses can be defined by the released neurotransmitter and the class of receptor activated by the transmitter. The major classes of neurotransmitter receptors are, on the one hand, cation-permeable excitatory receptors and, on the other hand, anion-permeable inhibitory receptors. Whereas tetrameric ionotropic glutamate receptors that include AMPA, kainate and NMDA receptors are the primary neurotransmitter receptors that mediate fast excitatory neurotransmission, the pentameric, Cys-loop GABA and glycine receptors encompass the major group of receptors that participate in fast inhibitory neurotransmission. There are additional Cys-loop receptors, however, that are selective for cations, and these include the excitatory acetylcholine and serotonin receptors. Trimeric ATP-gated P2X receptors, together with the similarly trimeric yet amino acid sequence disparate acid-sensing ion channels define a final class of cation permeable receptors present in the central nervous system.
To resolve fundamental questions of receptor architecture and molecular mechanism, my research group has embarked on studies of neurotransmitter receptors using x-ray crystallographic, electrophysiological and biochemical methods. We are particularly interested in understanding the mechanism by which agonist binding leads to receptor activation, the molecular principles that underlie receptor desensitization or inactivation, and the chemical and structural basis for ion selectivity, ion channel block and allosteric modulation of receptor activity. Over the past several years we have elaborated the atomic structures of intact trimeric acid sensing ion channels and ATP-gated P2X receptors, tetrameric AMPA receptors and pentameric Cys-loop receptors in multiple conformational states and in complexes with a wide array of agonists, antagonists, toxins, ions and allosteric modulators. Here I will define the overall architectures of these receptors and provide molecular mechanisms for their activities at chemical synapses that are grounded in experimental structural data at atomic resolution.

How are memories represented and recollected by the human brain?

E.A. Maguire

Wellcome Trust Centre for Neuroimaging, University College London, London, UK

We are endlessly fascinated with memory – we desire to improve it and fear its loss. While it has long been recognised that brain regions such as the hippocampus are vital for supporting memories of our past experiences, we still lack fundamental knowledge about the mechanisms involved. This is because studying the neural signatures of memories in vivo in humans presents a significant challenge. However, recent developments in high-resolution structural and functional magnetic resonance imaging coupled with advanced analysis methods now permit access to hippocampal processing that has hitherto been precluded in humans. In this talk I will describe how the application of 'decoding' techniques to brain imaging data is now beginning to disclose how individual memory representations develop and change, while also illuminating why some people have clearer memories than others, and why confusion about past experiences characterises normal aging and pathological states.

Rho proteins in cardiovascular physiology and diseases

G. Loirand

Inserm UMR_S1087, Nantes, France

Small G proteins exist in eukaryotes from yeast to human and constitute the Ras superfamily comprising more than 100 members. This superfamily is structurally classified into five families: the Ras, Rho, Rab, Arf and Ran families that control a wide variety of cell and biological functions through highly coordinated regulation processes. Among them, proteins of the Rho family are initially described as master regulators of the actin and microtubule cytoskeletons, thus regulating numerous cellular functions, including migration, membrane trafficking, adhesion, polarity and cell shape changes. However, increasing evidence has accumulated to identify Rho proteins and their regulators as key players of the cardiovascular physiology that control a large panel of cardiac (heart rhythm, contraction, hypertrophy) and vascular functions (angiogenesis, vascular permeability, vasoconstriction).
Indeed, basal Rho protein activity is required for homeostatic functions in physiological conditions, but sustained over-activation of Rho proteins or spatiotemporal dysregulation of Rho signalling pathways has pathological consequences in the cardiovascular system. Both pharmacological studies, genetic approaches in human, mouse models with targeted mutations in Rho proteins or regulators genes enabled the analysis of Rho protein functions in vivo, demonstrating their involvement in the pathogenesis of several diseases, including hypertension, coronary vasospasm, stroke, atherosclerosis, heart failure and diabetes. Accordingly, Rho protein signalling pathway and Rho proteins effectors such as Rho kinases are considered as important new pharmacological targets for the next generation of therapeutic agents in cardiovascular medicine. The primary object of this lecture is to provide a comprehensive overview of the current progress in our understanding of the role of Rho proteins and their regulators in cardiovascular physiology and pathologies and describing challenges for the future.

Sensing, signaling and sorting pathways in kidney epithelial cells

D. Brown, T.G. Paunescu, R. Bouley, S. Breton and H.A. Lu

Center for Systems Biology and Division of Nephrology/Program in Membrane Biology, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

Maintaining tight control over body fluid and acid/base homeostasis is essential for human health and is a major function of the kidney. This presentation will briefly outline new findings that have emerged over the past 2 or 3 years related to the function of two distinct cell types in the kidney collecting duct that are highly specialized to regulate water reabsorption (principal cells) and acid/base balance (intercalated cells) (1). Our work addresses the cell biological and signaling mechanisms that allow these cells to maintain systemic homeostasis by responding to physiological variations in plasma osmolality/volume and pH.

Principal cells: The antidiuretic hormone vasopressin (VP) and its receptor, the V2R, play a central role in regulating the urinary concentrating mechanism by stimulating accumulation of aquaporin 2 (AQP2) water channels in the plasma membrane of collecting duct principal cells (1). This increases epithelial water permeability and allows osmotic water reabsorption to occur. Knowledge of the basic V2R signaling pathways and their effect on AQP2 trafficking in epithelial cells is critical for the development of new therapeutic strategies for diseases such as nephrogenic diabetes insipidus, in which VP signaling is defective. We will summarize efforts to bypass defective V2R signaling in principal cells to induce AQP2 plasma membrane accumulation with agents such as sildenafil citrate and statins, and with the hormone calcitonin. A novel chemical screening assay is currently being used to identify new compounds that may be useful to regulate AQP2 trafficking in the context of urinary concentrating disorders. Finally, the potential role of AQP2 in renal development via an interaction with integrins will be discussed (3).

Intercalated cells: Urinary acidification due to the activation of intercalated cells is also critical to organ function, and defects lead to several pathological conditions in humans. We are striving to understand how these “professional” proton secreting cells respond to cellular and environmental cues, and some key work in this area was summarized in a recent review (2). One potential signaling pathway that intercalated cells might use to detect acid/base imbalances involves the soluble adenylyl cyclase, sAC, which could function as a luminal bicarbonate sensor in renal tubules to regulate acid/base homeostasis (6). By generating cAMP in response to elevated tubular bicarbonate, this pathway results in apical plasma membrane accumulation of the vacuolar H+ATPase (V-ATPase) (7), which increases acid secretion in an attempt to reduce systemic acidosis caused by inappropriate bicarbonate excretion. Other stimuli for proton secretion in these cells include, but are not limited to, aldosterone and angiotensin II.

As part of this work, we generated mice that express EGFP in their intercalated cells, driven by the promoter of the B1 V-ATPase subunit (5), as well as mice that lack specific V-ATPase subunits. These animal models, as well as intercalated cells isolated from our EGFP-expressing mice by fluorescence activated cell sorting are being used for various studies, including proteomic (4) and gene expression analysis, cell specific signaling studies, kidney function analysis, and differentiation pathways. Some of this recent and ongoing work will be addressed in this presentation.

Cortical HCN channels: function, trafficking and plasticity

M.M. Shah

UCL School of Pharmacy, London, UK

The hyperpolarization-activated cyclic nucleotide gated (HCN) channels are voltage-gated ion channels that are active at rest and are important for determining the intrinsic membrane properties of neurons. Four HCN subunits (HCN1-4) have been cloned, with HCN1 predominantly expressed in the cortex. These subunits are abundant in cortical pyramidal neuron dendrites but can also be located in synaptic terminals and axons. In this lecture, I will highlight work on the involvement of these channels in dendritic excitability, synaptic release and epileptogenesis in the entorhinal cortex (EC), an area of the brain involved in normal physiological processes such as spatial navigation and cognition as well as pathophysiological conditions such as epilepsy. I will also present work on the distinct molecular mechanisms underlying trafficking of these channels to dendritic and pre-synaptic compartments. This lecture should, thus, provide an insight into the role of these channels in regulating cortical neuronal function and the potential consequences of this for cognition and epilepsy.

L32

Respiratory and neural consequences for fish of a warmer and more carbonated future

G.E. Nilsson

Department of Biosciences, University of Oslo, Oslo, Norway

Average sea-surface temperature and the amount of CO_2 dissolved in the ocean are rising due to increasing concentrations of atmospheric CO_2. Many coral reef fishes appear to be living close to their thermal optimum, and for some of them, even relatively moderate increases in temperature (2 - 4°C) lead to significant reductions in aerobic scope (i.e. the difference between resting and maximum rates of oxygen uptake). Reduced aerobic capacity could affect population sustainability since less energy can be devoted to feeding and reproduction. Coral reef fish seem to have limited capacity to acclimate to elevated temperature as adults, but recent research shows that developmental and transgenerational plasticity occur, which might enable some species to adjust to rising ocean temperatures. A mayde even greater worry is that, even at maintained water temperatures, predicted future rises in ocean CO_2 levels have been found to alter sensory responses and behaviour of marine fishes. Changes include increased boldness and activity, loss of behavioural lateralization, altered auditory preferences and impaired olfactory function. It has been found that impaired olfactory function makes larval coral reef fish attracted to odours they normally avoid, including ones from predators and unfavourable habitats. These behavioural alterations have significant effects on mortality that may have far-reaching implications for populations. However, the underlying mechanism linking high CO_2 to these diverse responses has been unknown until recently. I will present results showing that abnormal olfactory preferences and loss of behavioural lateralization exhibited by two species of larval coral reef fish exposed to high CO_2 can be rapidly and effectively reversed by treatment with an antagonist of the GABA-A receptor. GABA-A is a Cl- / bicarbonate channel and a major neurotransmitter receptor in the vertebrate brain. These results indicate that high CO_2 interferes with brain ion-balance and thereby neurotransmitter function, a hitherto unrecognized threat to marine populations and ecosystems. Given the ubiquity and conserved function of GABA-A receptors, this predicts that rising CO_2 levels could cause sensory and behavioural impairment in a wide range of marine animals.

Regulation of tonic inhibition in the hippocampus

M. Walker[1], I. Pavlov[1], A.C. Linthorst[2] and A. Semyanov[3,4]

[1]UCL Institute of Neurology, London, UK, [2]Henry Wellcome Laboratories for Integrative Neuroscience and Endocrinology, University of Bristol, Bristol, UK, [3]RIKEN Brain Science Institute, Wako-shi, Japan and [4]Nizhny Novgorod State University, Nizhny Novgorod, Russian Federation

Activation of GABA(A) receptors (GABARs) produces two forms of inhibition: phasic inhibition generated by the rapid, transient activation of synaptic GABARs by presynaptic GABA release, and tonic inhibition generated by the persistent activation of perisynaptic or extrasynaptic GABARs, which can detect extracellular GABA. Tonic GABAR-mediated currents are present in multifarious neuronal subtypes in the hippocampus, but are predominantly mediated by alpha5 subunit-containing and delta subunit-containing GABA(A) receptors.

These tonic currents have a profound effect upon neuronal excitability, and can be regulated over different time scales through receptor expression, receptor modulation and changes in extracellular GABA concentrations. This talk will present recent evidence on the regulation of extracellular GABA in the hippocampus and its impact on tonic inhibition, and on how extrasynaptic GABA(A) receptor characteristics contribute to the their computational role.

In vivo, GABA concentrations in the hippocampus (measured using microdialysis) under resting conditions are of the order of 100 nM, and even lower concentrations are detected by principal neurons. The tight regulation of extracellular GABA is maintained by effective GABA transporters: GAT1 which mainly regulates GABA originating from the synaptic pool, and GAT3 which predominantly regulates GABA originating from the extrasynaptic pool. GAT3 can also contribute to regulation of synaptically released GABA when GAT1 is blocked or when network activity increases.

The low concentration of GABA during resting condition means that a substantial proportion of the tonic current is mediated by spontaneously opening GABARs. These spontaneously opening GABARs maintain a lower limit to tonic inhibition and permit regulation through modulators even when GABA is not being detected. Spontaneously opening receptors also have a different pharmacology from openings due to GABA binding.

Increases in synaptic activity can raise the extracellular GABA; during seizure-like activity, the GABA can rise 3-4 fold. This results in increases in tonic currents, both through direct activation of GABARs and also through GABA(B) receptor-dependent enhancement of extrasynaptic GABAR function. This increase in tonic currents generally inhibits neurons, but can have biphasic effects in interneurons in which the GABAR reversal potential is depolarizing relative to resting membrane potential.

The computational effect of increasing extrasynaptic GABR activation is partly dependent upon the current-voltage characteristics of the receptors, which show marked outward rectification. This results in a shunting effect of tonic inhibition at spiking threshold with a much lesser effect on noise at resting membrane potential. The consequence of this outward rectification is that tonic currents in pyramidal cells affect offset of the input-output function of neurons without affecting gain. In contrast, synaptic inhibition affects both offset and gain.

In temporal lobe epilepsy, in which there is a shift from phasic to tonic inhibition, the input-output functions of neurons would be expected to have maintained off-set but increased gain. We hypothesize that such a change results in network instability, contributing to the sporadic occurrence of seizures.

The role of GABAergic interneurons in controlling information flow through the cerebellar cortex

B. Stell

C.N.R.S., Paris, France and Université Paris Descartes, Paris, France

The coordinated simple spike activity of neighboring Purkinje cells has been studied extensively using electrophysiological techniques in both awake animals and cerebellar slices (Person and Raman, 2012). However, electrophysiological recordings have restricted the spatial extent to which this coordination has been examined. We demonstrate that fluorescent calcium indicators can be used as a highly effective readout of simple spike activity, and allow the monitoring of this activity in many Purkinje cells simultaneously. By imaging multiple Purkinje cells, a degree of spatial information is retained and it becomes possible to probe components of the cerebellar circuit and view how information flows out of the cerebellar cortex via these cells. Using this method to examine spontaneous Purkinje cell activity, we find highly coordinated pauses between cells that is dependent upon GABA-A receptor activation. Furthermore, activation of molecular layer interneurons with either electrophysiological or channelrhodopsin stimulation, induces pauses that are coordinated between neighboring Purkinje cells. These coordinated pauses are likely play a large role in controlling spiking of the deep cerebellar

nuclear cells which in turn output the information from the cerebellum.

Metabolic hormones turn-on GABA-A channels that generate tonic inhibition

B. Birnir, Z. Jin and S. Korol

Department of Neuroscience, Uppsala University, Uppsala, Sweden

The hippocampus is an established center for memory and learning but it is less well known that it also governs body physiology. It is, therefore, not surprising that the hippocampus can sense physiological parameters and robustly expresses a number of receptors for a variety of molecules including metabolic hormones (1). We, nevertheless, know relatively little about how the metabolic hormones modulate hippocampal neuronal function. Do the hormones modulate the excitatory or the inhibitory system or both? Or, when there is too much or too little of these molecules e.g. insulin or glucagon-like peptide-1 (GLP-1), do these hormones then contribute to or even cause disease states, like decreased memory formation, increased seizure frequency or strength or even neuronal death like can occur in dementia, Alzheimer disease, epilepsy, diabetes and multiple sclerosis? We have studied the effects of insulin and GLP-1 on GABA-activated currents in rat hippocampal pyramidal neurons. The insulin receptor is prominently expressed in the hippocampus suggesting that insulin regulates hippocampal function (1). We have identified a molecular target of insulin signaling in the CA1 pyramidal neurons, the output neurons of the hippocampus (2). In acute hippocampal brain slices, physiological concentrations of insulin (1 nM) "turn-on" new, extrasynaptic GABA-A receptors in the CA1 pyramidal neurons. These channels are activated by more than a million times lower GABA concentration (EC50 17 + 4 pM) than the synaptic channels and generate tonic currents. The channels are inhibited by GABA-A receptors antagonists and have novel pharmacology as flumazenil and zolpidem are inverse agonists. The results are consistent with the channels containing at least $\alpha5\beta\gamma2$ GABA-A receptor subunits. Activation of the channels results in decreased action potential firing. Importantly, our results show that tonic rather than synaptic conductances regulate basal neuronal excitability when significant tonic conductance is expressed. GLP-1, another metabolic hormone, is secreted by intestinal L cells. Application of GLP-1 (10 pM – 10 nM) or its analog exendin-4 (10 - 100 nM) evoked tonic currents and increased the frequency of synaptic GABA-activated currents as compared to control in the rat hippocampal CA3 pyramidal neurons. The neuronal membrane potential hyperpolarized upon GLP-1 application and the action potential frequency decreased. When GLP-1 was removed, the membrane potential depolarized back to the initial value and the action potential frequency recovered (n = 5). Our findings demonstrate an unexpected hormonal control of GABA-A receptor subtypes and excitability of hippocampal neurons. The results have implications for not only normal function but also diseases of the hippocampus.

SA4

Tipping the balance between cortical excitation and inhibition

O. Yizhar

Weizmann Institute of Science, Rehovot, Israel

Excitation and inhibition in neocortical circuits are finely tuned and the balance between them is tightly regulated. Multiple lines of evidence, from psychiatric disease patients and animal models of psychiatric disease, have led to the hypothesis that changes in the cellular balance between excitation and inhibition (E/I balance) could lead to the severe behavioral deficits associated with diseases such as epilepsy, autism and schizophrenia. To evaluate this hypothesis experimentally, we developed several new optogenetic tools that allow simultaneous modulation of neocortical excitatory and inhibitory neurons. Microbial opsin-based optogenetic tools allow genetically-encoded, light-based control of neural circuits in vivo. The use of microbial opsins as optogenetic tools requires robust delivery of the opsin gene products to the plasma membrane of targeted neurons, efficient modulation of targeted cells through in vivo light delivery and readout strategies for recording the electrophysiological and behavioral outcomes of optical manipulation. We created a set of engineered channelrhodopsins with distinct spectral and temporal properties and targeted these optogenetic tools to cortical excitatory or inhibitory neurons. With this approach, we bidirectionally modulated the cellular excitation-inhibition balance in the prefrontal cortex of awake, behaving mice. We found that elevation, but not reduction, of the cellular E/I balance within the medial prefrontal cortex leads to profound impairment in cellular information processing and is associated with both specific behavioral deficits and increased high-frequency power in the 30–80 Hz range. Our results demonstrate the utility of new optogenetic tools in modulating neural activity and provide support for the cellular E/I balance hypothesis in neuropsychiatric disease.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA5

Inflammation and GABA-A receptors

B. Orser

Physiology and Anesthesia, University of Toronto, Toronto, ON, Canada

Inflammation causes deficits in learning and memory deficits through mechanisms that remain poorly understood. I will present evidence that memory loss associated with inflammation involves the same receptors that mediate the memory blocking properties of a variety of drugs, including anesthetics and benzodiazepines. Our results show that key pro-inflammatory cytokines including interleukin-1β (IL-1β)

increase the activity of α5 subunit-containing γ- aminobutyric acid type A (α5GABAA) receptors. This increase in receptor activity reduces long-term potentiation, a synaptic correlate of memory, in hippocampal slices from wild-type mice. Further, IL-1β induced memory deficits were observed in WT but not Gabra5-/- mice. Collectively, the results show that α5GABAA receptor activity increases during inflammation and this increase is critical for inflammation-induced memory deficits.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Interplay between molecules of adaptive homeostasis and their interaction with hypobaric hypoxia

Q. Pasha

CSIR-Institute of Genomics and Integrative Biology, Delhi, India

High-altitude (HA), the elevation above 8,000 feet, is responsible for low partial pressure of air and as a consequence reduced blood arterial oxygen saturation (SaO2) in the body. Out of many characteristic features of the HA environment, it is the hypobaric hypoxia that has the main effect on living beings and is the chief driving force for major acclimatization and adaptive processes. When exposed to this environment body undergoes various physiological changes so as to maintain the O2 availability to the tissue.

The HA natives because of generations of inhabitation have acquired unique phenotypes. Compared to the HA natives, the lowland population when exposed to a similar environment reacts differentially. There are sojourners with no signs of discomfort whereas few of them experience discomfort and develop mountain disorders. Among the various mountain disorders, HA pulmonary edema (HAPE) is a unique disorder of concern especially to sojourners. It is a multi-factorial trait characterized by hypoxic pulmonary vasoconstriction, endothelial dysfunction and intra-vascular fluid retention that are contributed effectively and equally by genetic and epigenetic factors. Hence, any kind of perturbation in the regular O2 supply of the body disturbs pathways maintaining vascular and adaptive homeostasis resulting in organ dysfunction. As a consequence, the genes of these pathways become obvious candidates and hence, *Apelin (APLN), Apelin receptor (APLNR), Endothelial nitric oxide synthase (NOS3)* and *HIF-prolyl hydroxylase 2 (EGLN1)* have been elucidated in HAPE pathophysiology and adaptation. The human ethical committees of Institute of Genomics and Integrative Biology and SNM hospital have approved the study.

In a comparative study of healthy highlanders (HLs) and sojourners i.e. HAPE-free controls (HAPE-f) and HAPE-patients (HAPE-p), the distribution of alleles, haplotypes, interacting genotypes, epigenetic regulations and their association with clinical and biochemical parameters provided some interesting insights. The healthy HLs and HAPE-f had significantly higher level of SaO_2 compared to HAPE-p (P<0.0001). Likewise, pulmonary arterial systolic pressure (PASP) was also significantly lower in these healthy subjects. The higher SaO2 and lower PASP levels clearly signify better physical capabilities in health and vice versa in diseased state. Analysis of genotype distribution revealed significant differences in the SNPs of *EGLN1, APLN, APLNR* and *NOS3* with respect to adaptation and HAPE. The 4.55-fold upegulated *EGLN1* expression in HAPE-p (P=0.0084) when compared with HAPE-f suggested that this upregulation caused dysfunctioning of HIF1α prohibiting downstream genes from maintaining cellular O2 homeostasis. Furthermore, the risk variants rs1538664A, rs479200T, rs2486729A, rs2790879G, rs480902C, rs2486736A, and rs973252G and the respective haplotypes A-T-A-G-C-A-G, G-T-A-G-C-A-G, and G-T-G-T-C-G-A, which were over-represented in HAPE, correlated with decreased SaO2 level and increased EGLN1 expression.

The 11.7 Kb long APLN sequencing showed the presence of CpG islands. The significantly higher percentage of methylation in these islands in HAPE-p seems to be responsible for downregulation of APLN expression (P>0.05). The *APLN* and *APLNR* expression was down-regulated by 3.52- and 2.35-fold in HAPE-p (P=0.003 and 0.068). Similarly, the APLN-13 levels were down-regulated in the patients compared to HAPE-f and HLs (P<0.0001). Further, analysis of risk variants *APLN* rs3761581G, rs2235312T and *APLNR* rs11544374A revealed association with decreased APLN levels and gene expression (P<0.05). As APLN-APLNR system brings its effect through activation of NOS3; therefore, the role of NOS3 was perceptible. *NOS3* expression was upregulated by 5.2-fold in HLs (P=0.0015) when compared to HAPE-f and NO levels were 57.67 ±35.5 μmol/L, 73.75 ±49.9 μmol/L and 122.45 ±103.3 μmol/L in HAPE-p, HAPE-f and HLs (P<0.0001). The significant down-regulation of APLN and NO suggested the disruption of APLN-APLNR system in HAPE. Of note, the genotypes interactions between the genes depicted few best disease pre¬dicting models in HAPE (P<0.05).

To conclude, the association of EGLN1 SNPs rs1538664, rs479200, rs2486729, rs2790879, rs480902, rs2486736, and rs973252 with SaO2 levels and *EGLN1* expression, *APLN* SNPs rs3761581, rs2235312 and *APLNR* SNPs rs11544374 with APLN levels and *APLN* expression and *NOS3* SNPs rs7830, rs1799983 and 4b/4a with NO levels and *NOS3* expression portrayed the functional consequences of these variants at HA. In addition, this extreme environment influences the epigenetic regulation as is evident through higher methylation of *APLN*.

Mild hypoxia regulate the property/function of neural stem cells *in vitro*

L. Zhu, X. Huang and M. Fan

Department of Cognitive Sciences, Institute of Basic Medical Sciences, Beijing 100850, China, Beijing, China

Neural stem cells(NSCs) exist widely in the developing and adult mammalian brain, which are self-renewing and can differentiate into neurons, astrocytes or oligodendrocytes in vitro. The proliferation of NSCs in vitro has been reported to be regulated by various factors. However, growing studies by the use of oxygen microelectrodes show that the mammalian embryo developed in uterus with a hypoxic environment and neural stem or progenitor cell in the brain are also with hypoxic niche. The mean oxygen concentration is about 1-5% in tissues. To date, in vitro studies using NSCs have primarily been done under atmospheric conditions of 20% oxygen as the standard culture system. This indicates that traditional oxygen concentration in cell culture system may be a hyperoxia environment but not a condition of “physiological hypoxia” to most of cells in situ. Herein, we performed a series of experiments to testify whether the exogenous hypoxia could impact the

growth of NSCs and their function? How hypoxia regulates the property of NSCs? And then what's the molecular involved in this process?

Firstly, we compared the different exogenous oxygen content on the NSCs' growth in vitro. The embryo-derived neural stem cells were cultured under the 3%,10% and 20% oxygen concentration. There are about 2- to 5- fold increases in the number of NSCs cultured after exposure to hypoxia condition compared to normal condition. Especially, mild hypoxia dramatically promotes the proliferation of NSCs and decreases its apoptosis. The above results were further confirmed in both mouse and human-derived neural stem cells from embryo and adult, which revealed that neural stem cells in vitro prefer 1 to 10% oxygen culture environment. Thus, Mild hypoxia (1-10% oxygen) is a much more potent trigger to promote the proliferation of adult stem cells than normoxia (20% oxygen), suggesting mild hypoxia is a novel method for expansion of various adult stem cells in vitro.

We further examine the differentiation ability of NSCs expanded under hypoxia conditions in vitro. The NSCs cultured in hypoxia (3% O2) displayed an increase in the percentage of neurons. Especially the percentage of TH-positive neurons differentiated from NSCs in lowered oxygen increased significantly. Dopamine (DA) content in supernatant of culture hypoxia group was the double of that in the normoxia group. This study may also offer a new approach to yield DA neurons by using a physical factor.

The data above demonstrate that low oxygen significantly promotes the proliferation of NSCs and supports the property of self-renewal in vitro. However, the molecular mechanisms underlying this hypoxia-driven proliferation are unknown. To address this question, a cDNA microarray containing 5704 rat genes was used to characterize the gene expression pattern during hypoxia-driven proliferation of NSCs. Of the 5704 genes examined, 49 were down-regulated less than 0.5-fold and 22 were upregulated more than twofold at 24 h. At 72 h, 60 genes were upregulated and 11 were downregulated. Among the 71 differentially expressed genes identified at 24 h, the greatest number were involved in glycolysis and metabolism (36%), followed by transcriptional regulation (15%) and cell organization and biogenesis (10%). The NSCs under low oxygen consumed more glucose and produced energy by glycolysis. The information gained from gene expression and metabolic changes of NSCs under low oxygen conditions will provide new approaches for the evaluation of NSCs as potential in vivo cellular therapeutics.

Without doubt, Hypoxia-inducible factor (HIF)-1, which is one of the key transcription factors under hypoxia, play an important role mediating a variety of adaptive cellular and systemic responses to hypoxia by regulating the expression of more than 50 different genes. The hypoxia-induced Small non-coding RNA (ncRNA) was investigated and shown involved in regulation of NSC proliferation. Results revealed that 15 small RNAs were up-regulated at least threefold and 11 were down-regulated in NSCs after subjected to hypoxic conditions. Especially, MiR-210 was observed to be highly expressed in NSCs in a time- and oxygen-dependent manner, and is directly regulated by HIF-1a. Hypoxia-induced expression of miR-210 may be involved in regulating apoptosis and proliferation of NSCs under hypoxia.

In summary, our studies demonstrate that mild hypoxia not only promote the self-renew ability of NSCs in vitro, but also increase their differentiation ability into neurons. Therefore, via expansion of NSCs in vitro or modification of it's' property in situ, mild hypoxia could become a potential approach for allograft cell transplantation. We hope these findings will aid in the transplantation of NSCs to treat neural degenerative diseases such as Parkinson's disease and brain trauma.

Andean, Tibetan and East African patterns of adaptation to high-altitude hypoxia

C.M. Beall

Case Western Reserve University, Cleveland, OH, USA

Low ambient partial pressures of oxygen at high altitudes result in low alveolar and arterial partial pressures that stress physiological oxygen delivery systems. People moved onto high-altitude plateaus in three areas of the world in the past 10,000 or more years, resulting in independent natural experiments in adaptation and evolution. Unexpectedly, the high-altitude native populations of the Andean, Tibetan and East African plateaus have different suites of adaptive traits and their genomes show different signatures of natural selection despite the common stress. This talk presents aspects of the three patterns of adaptation, their relative costs and benefits, and evidence that they result from evolutionary processes. The variety of responses to the same stress expands our understanding of oxygen homeostasis.

Work capacity and selected physiological factors by ethnicity and residential altitude – cross-sectional studies of 9- to 10-year-old children in Tibet

B. Bianba

Tibet University Medical College, Lhasa, China and University of Oslo, Oslo, Norway

The objective of the present study is to compare work capacity (maximal power output) and selected physiological factors (arterial oxygen saturation and heart rate at rest and during maximal exercise, hemoglobin concentration and forced vital capacity) in groups of native Tibetan children living at different residential altitudes (3,700 vs. 4,300 m above sea level) and across ethnicity (native Tibetan vs. Han Chinese children living at the same altitude of 3,700 m). The maximal power output was 2.68 ±0.49 W/kg in native Tibetans at 3,700 m, which was 3.5% higher than Han Chinese at 3,700 m (2.59 ±0.48 W/kg), and 19.6% higher than native Tibetans at 4,300 m (2.24 ±0.56 W/kg). The superior work capacity in native Tibetans vs. Han Chinese may reflect a better adaptation to life at high altitude. Tibetans at a lower residential altitude of 3,700 m demonstrate a better work capacity than residents at a higher altitude of 4,300 m. The associations between residential altitude and ethnicity with maximal power output could not be fully explained by the measured physiological factors. However, several physiological parameters explained the variance in work capacity, including higher arterial oxygen saturation and higher forced vital capacity.

Mechanisms of thermo- and chemosensing in TRP channels

T. Voets

Laboratory of Ion Channel Research, KU Leuven, Leuven, Belgium

The ability to sense environmental temperatures and to avoid noxious heat or cold is crucial for the survival of all organisms. In mammals, sensory neurons from dorsal root and trigeminal ganglia convey thermal information from the skin, mouth and nose to the central nervous system. Recent evidence has established that thermoTRPs, a subset of the TRP superfamily of cation channels, act as primary temperature sensors in cold- and heat-sensitive neurons. The gating of these thermoTRPs exhibits strong temperature dependence, leading to steep changes in inward current upon heating or cooling. Moreover, several natural or synthetic compounds act as ligands of thermoTRPs, thereby creating sensations of cold or hot independent of actual changes in temperature.
In this presentation, I will present our latest insights in how these channels detect and integrate thermal and chemical stimuli, and discuss the in vivo consequences of thermoTRP gating .

Our work on thermoTRPs is supported by grants from the Belgian Federal Government (IUAP P7/13), the Research Foundation-Flanders (F.W.O.) (G.0565.07), and the Research Council of the KU Leuven (GOA 2009/07 PF-TRPLe).

Physiological functions of melastatin TRPs in the heart

Z. Yue, J. Xie, X. Qin, B. Sun, Y. Zhang, J. Du, B. Liang and L. Yue

Cardiology/Cell Biology, University of Connecticut Health Center, Farmington, CT, USA

The transient receptor potential channels (TRP) play important roles under various physiological/pathological conditions. In the heart, several members of TRPC channel subfamily have been demonstrated to play a role in hypertrophy and heart failure. In the TRPM subfamily, TRPM7, TRPM4, and TRPM2 have been shown to be functionally expressed in the heart. Patients carrying TRPM4 mutations develop A-V block. We have demonstrated previously that TRPM7 mediated Ca2+ plays an important role in fibrogenesis and human atrial fibrillation. Here we show that in transverse aortic constriction (TAC) induced hypertrophy and heart failure mouse model, TRPM7 is highly up-regulated. Deletion of Trpm7 significantly increases heart performance in comparison with the wild type (WT) mice after TAC. The ejection fraction is significantly larger and the ratio of heart versus body weight is much smaller in TRPM7-KO mice compared to WT mice after TAC. Moreover, depletion of Trpm7 significantly decreases collagen production and fibrosis formation in TAC induced heart failure mice. Taken together, deletion of Trpm7 can protect against TAC induced heart failure.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Allosteric models and thermo sensitivity in TRPM8 channels

R. Latorre[1], C. Gonzalez[2], D. Baez-Nieto[3] and N. Raddatz[4]

[1]Centro Interdisciplinario de Neurociencia, Universidad de Valparaiso, Valparaiso, Chile, [2]Centro Interdisciplinario de Neurociencia, Universidad de valparaiso, Valparaiso, Chile, [3]Centro Interdisciplinario de Neurociencia, Universidad de Valparaiso, Valparaiso, Chile and [4]Centro Interdisciplinario de Neurociencia, Universidad de Valparaiso, Valparaiso, Chile

TRPM8 channels are a polymodal receptors activated by voltage, low temperatures and agonists. The structural data suggests that the distal C-terminus (1064–1104 amino acid residues) form a coiled-coil motif. Our aim was to investigate the importance of this structure in the thermo-sensitivity of TRPM8. TRPM8 wild type and deletion mutants of the coiled-coil region of this channel were cloned and expressed in Xenopus oocytes. Macroscopic currents were recorded by patch-clamp technique in cell-attached configuration at different temperatures (10°C- 40°C). An analysis of the conductance-voltage curves determined from tail currents showed that values of the voltage at which the open probability is 0,5 (V1/2) saturate at high and low temperatures. These results and limiting slope analysis of the open probability–voltage curves demonstrated that TRPM8 channel gating is best explained using an allosteric gating model for both voltage and temperature dependence. On the other hand, gradual deletions of the coiled-coil region (from 1064 to 1104 residues) promoted a gradual decrease in the temperature sensitivity of TRPM8 channel, without affecting the voltage dependence. The decrease in the enthalpy promoted by gradual deletions of the distal C-terminus suggests that coiled-coil region is a structural determinant of the thermo sensitivity in TRPM8 channels. Our results also indicate that the voltage and temperature sensors are localized in different structural domains.

Transient receptor potential channels in sperm physiology

C.L. Trevino

Genetica del Desarrollo y Fisiologia Molecular, Instituto de Biotecnoligía, Universidad Nacional Autonoma de Mexico, Cuernavaca, Morelos, Mexico

Fertilization is a fundamental biological process that produces a new and unique individual, enabling species preservation and evolution through sexual reproduction. Sperm cells are uniquely equipped to reach, recognize and fuse with the egg. To perform such diverse tasks, spermatozoa must be prepared to face the challenges presented by their constantly changing surroundings. Thus, sperm cells heavily rely on sophisticated signal transduction mechanisms to swim in a directed fashion, and to adjust to changing environmental conditions.

Ion-mediated signal transduction is particularly important in sperm cells, as they essentially lack the protein synthesis capabilities required for signaling mechanisms normally available to other cell types. Accordingly, fluctuations in intracellular Ca^{2+} concentrations ($[Ca^{2+}]_i$) trigger and/or regulate some of the main sperm functions involved in fertilization. These include motility, capacitation (a process that confers fertilization capability), and the acrosome reaction or AR (a Ca^{2+}-dependent exocytotic event required for fertilization). The extent of participation and the specific roles of the many putative Ca^{2+} channels thought to mediate sperm functions still remain to be elucidated. Based on studies conducted on various other cell types, Transient Receptor Potential (TRP) channels are known to be a functionally diverse family of Ca^{2+} channels; they modulate $[Ca^{2+}]_i$ in response to various thermal, chemical or mechanical stimuli. Members of the M (Melastatin) subfamily (TRPM) participate in sensory physiology, both at the cell and organismal levels. For example, they are responsible for sensing, among other stimuli, changes in temperature, osmolarity, voltage and/or pH. Importantly, these channels are often sensitive to more than one stimulus and are thus regarded to function as signal integrators. While this particular feature is conceivably of great value for sperm cells embarking on their adventurous journey towards the egg, the involvement of TRPM channels in sperm physiology has not been established. We therefore centered this work on the characterization of TRPM8 –a Ca^{2+} channel known to open upon temperature decrease– both in mouse (CD-1 strain) and in human sperm. Using specific antibodies, we first show that TRPM8 immunolocalizes to the head and to the flagellum in both species (n=3); the expression of this channel was confirmed by Western blot analyses (n=3) in both species. We then studied the functionality of sperm TRPM8 by: (a) measuring $[Ca^{2+}]_i$ using fluorescent dyes; (b) measuring AR induction using standard methodologies for mouse (1) and human (2) sperm; and (c) measuring ion currents making use of the recently established sperm patch clamping technique (3), which is performed on a unique cytoplasmatic extension of sperm cells known as the cytoplasmic droplet. We found that menthol (a TRPM8 agonist) elevates$[Ca^{2+}]_i$ inducing the AR in a dose-dependent manner both in human and mouse sperm (IC_{50} = 300 and 500 μM, respectively). BCTC (N-(4-t-Butylphenyl)-4-(3-Chloropyridin-2-yl) tetrahydropyrazine-1(2H)-carboxamide) and capsazepine (two TRPM8 antagonists) inhibit the menthol-induced AR in both species (n=3). In human sperm these inhibitors did not interfere with the AR induced by two of the physiological inductors, namely ZP3 (zona pellucida protein 3) and progesterone, suggesting that TRPM8 activation triggers the AR through a different signaling pathway than these physiological inductors (2). The effect of low temperature was also tested in mouse sperm, where it induced an increase in $[Ca^{2+}]_i$. However, in this species, BCTC and capsazepine did inhibit –at least partially– the ZP3- and progesterone-induced AR (n=3). Consistently, we found that spermatozoa from TRPM8 knockout mice do not undergo the menthol-induced AR that is sensitive to TRPM8 antagonists (n=3). Patch clamp experiments were exclusively conducted in testicular mouse spermatozoa, revealing currents triggered by menthol, icilin (another TRPM8 agonist), and low temperature. These currents were inhibited by BCTC and capsazepine (n=3), confirming they are due to TRPM8 activity (1). Further studies are needed to elucidate the precise roles that TRPM8 channels may play during fertilization, but the present confirmation of their expression and functionality in sperm cells places them as likely signal integrators in Ca^{2+}-mediated signaling. As such, these channels become attractive subjects of investigation as plausible participants in chemotaxis and thermotaxis –two processes whose involvement in fertilization is still awaiting confirmation.

SA14

Role of TRPA1 in gastrointestinal motility

H. Ito, K. Nozawa, H. Doihara, R. Kojima, E. Kawabata-Shoda, Y. Keto and T. Yokoyama

Pharmacology Research Labs., Drug Discovery Research, Tsukuba, Ibaraki, Japan

Transient receptor potential ankyrin1 (TRPA1) is a non-selective cation channel activated by cold stimuli under 17 °C, mechanosensation, and pungent irritants such as allyl isothiocyanates (AITC) and cinnamaldehyde (CA). TRPA1 is located in the sensory terminals of nociceptive fibers in their target organs, such as urinary bladder and the small intestine, and the activation of TRPA1 elicited contractile responses in these organs. However, little is known about the functional role of TRPA1 in non-neural tissues, especially in the gastrointestinal tract.

We demonstrated that TRPA1 is highly expressed in enterochromaffin (EC) cells in enteric mucosa, and that TRPA1 stimulation with agonists evokes the release of 5-hydroxytryptamine (5-HT) from EC cells.[1)] This could produce contraction of guinea-pig ileum by stimulating serotonergic mechanisms. The release of 5-HT from the mucosa and the stimulation of $5\text{-}HT_3$ receptors located in the myenteric plexus may contribute to the TRPA1 agonist-induced contractions in guinea pig ileum. Gastrointestinal (GI) dysmotility and visceral pain/discomfort are the main symptoms of irritable bowel syndrome (IBS). The neurotransmitter 5-HT has been shown to be involved in the pathophysiology of IBS. Especially, postprandial plasma level of 5-HT in patients with IBS with constipation (IBS-C) has been reported to be lower than that in healthy subjects.

As mentioned above, we originally found that TRPA1 receptors were expressed on EC cells in GI tract, which are 5-HT releasing cells.[1)] Therefore, TRPA1 receptor is expected to be involved in GI motility and to be a novel target of the drug for IBS-C.

ASP7663 has been newly synthesized in Astellas Pharma Inc. as a novel selective TRPA1 receptor agonist. The compound activated human, rat, and mouse TRPA1 receptors with EC_{50} values of 0.51(0.40-0.66), 0.54(0.40-0.72), and 0.50(0.41-0.63)

μM, respectively. We examined the effect of ASP7663 on constipation using an experimental rodent model of IBS-C.[2] Further, the effect of ASP7663 on visceral pain response was also examined. ASP7663 showed anti-constipation effects in Loperamide-induced delay of colonic transit in mice, and analgesic effect in colorectal distension-induced visceral pain responses in rat.[3] Consequently, ASP7663 is expected to be a novel and promising therapeutic agent for IBS-C with substantial efficacy in relieving on both constipation and visceral pain symptoms Our results indicate that TRPA1 acts as a sensor molecule for EC cells and may regulate the gastrointestinal function. TRPA1 activation by ingested food containing pungent ingredients, such as mustard oil and cinnamon oil, could promote gastrointestinal motility through these mechanisms. Furthermore, in case of functional GI disorder, such as IBS, TRPA1 receptor agonists hold promise as a beneficial treatment.
In addition, our research on the QGP-1 cell line, a new model for the investigation of TRPA1 function in the human EC cell,[4] and functional role of TRPA1 in GI motility in dog[5] would also be mentioned.

Vascular senescence and organ fibrosis

J. Maizel, R. Vasko, S. Xavier, J. Chen, J. Cao and M.S. Goligorsky

Medicine, Pharmacology, Physiology, New York Medical College, Valhalla, NY, USA

Multiorgan fibrosis commonly occurs in ageing mammals and its causes are not apparent. We have previously established a colony of mice with endothelial deletion of sirtuin 1 (SIRT1; SIRT1endo-/- mice) and noticed that these mice spontaneously develop traces of fibrosis in the kidneys and the heart and mount an exaggerated fibrotic response after challenge with stressors. Taking into the account the fact that SIRT1 becomes depleted in ageing, these findings raised the possibility of its participation in fibrosis of ageing. To address this possibility, we characterized the animal model of SIRT1endo-/-. Data showed that endothelial and endothelial progenitor cells exhibit higher levels of premature senescence, apoptosis, and reduced resistance to stressors, along with the impaired angiogenesis and reduced endothelium-dependent vasorelaxation. Morphologic examination of the heart and kidneys from these mice did not reveal any pathological changes in heterozygote animals, but showed a spontaneously developing mild patchy interstitial fibrosis in SIRT1endo-/- mice already at the age of 12 weeks. Quantitative PCR data demonstrated significantly higher expression of collagen I and a slightly increased collagen III under basal conditions. Echocardiography studies showed development of a mild diastolic dysfunction in 30 week-old SIRT1endo-/- mice. Applying a selection pressure on angiogenic and regenerative processes, we next examined adriamycin-induced cardiomyopathy and folate-induced nephropathy models. Data showed that trichrome staining, collagen I and III mRNA expression, as well as the short/long ratio of endoglin isoforms, a marker of senescence, were all elevated in SIRT1endo-/- mice. Folic acid-treated SIRT1endo-/- mice exhibited microvascular rarefaction, which was undetectable under basal conditions. It was previously reported that SIRT1 inhibition reduces MMP-14 mRNA abundance in cultured endothelial cells. We were able to reproduce these findings and showed that SIRT1endo-/- mice exhibited a 5-fold decrease in MMP-14 staining intensity compared to control animals and SIRT1 inhibition reduced MMP-14 protein abundance and matrylitic activity. Next, we examined other putative targets of MMP-14, endoglin and tissue transglutaminase (both normally cleaved by MMP-14), over-expression of both potentially contributing to pro-fibrotic program via type II TGF-β receptor and matrix proteins cross-linking, respectively. Inhibition of SIRT1 in HUVEC resulted in accumulation of endoglin Similarly, expression of cell-associated tissue transglutaminase was elevated in cells treated with SIRT1 inhibitor. Collectively, these findings confirmed that MMP-14 represents a novel target for SIRT1 and that depletion of the latter reduces MMP-14 expression with the resulting loss of proteolytic matrix-degrading properties of endothelial cells and subsequently decreased cleavage of endoglin and tissue transglutaminase. ConA has been previously shown to induce MMP-14. We confirmed this activity of ConA in vitro and showed that ConA effect was independent on the expression of SIRT1. Therefore, we next treated wild-type B6;129 mice with highly specific SIRT1 inhibitor III together with weekly intravenous injections of ConA, and compared those with mice receiving SIRT1 inhibitor III treatment alone. To validate the efficacy of this model, we performed quantitative real-time PCR and immunoblot analysis, which showed suppression of renal MMP-14 in the inhibitor-treated mice and its induction in ConA co-treated animals. In these mice, ConA treatment resulted in the reduction of proteinuria and significant prevention of fibrosis, as demonstrated by Masson's trichrome staining. The mRNA synthesis of collagen I and III did not differ between SIRT1 inhibitor III-treated and SIRT1 inhibitor III/ConA-treated mice, demonstrating that ConA does not directly affect synthesis of extracellular matrix (ECM), but rather stimulates the cleavage of ECM excess through induction of MMP-14. Moreover, the angiogenic sprouting and matrilytic activity of aortic rings cultured in 3D matrigel, both suppressed in mice receiving SIRT1 inhibitor alone, showed a dramatic increase in ConA-treated animals. This data confirms the pathogenetic role of suppressed MMP-14 in exaggerated fibrotic response of SIRT1endo-/- mice. It also suggests that SIRT1 depletion with ageing and propensity toward fibrosis are linked via this novel MMP-14 mechanism.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA16

Role of sirtuins in endothelial cell senescence

A. Cardús[1,2], A. Uryga[1] and J. Erusalimsky[1]

[1]Cardiff Metropolitan University, Cardiff, UK and [2]Universitat de Lleida, Lleida, Spain

Members of silent information regulator (Sir) proteins regulate lifespan in multiple models organism. The most studied sirtuin is sir2 in yeast, an NAD+- dependent deacetylase that remove acetyl groups from another protein, thereby regulating the biological function of their targets. In addition Sir2 appears to be a limiting component in yeast ageing. Due to their established role in controlling lifespan in lower organism,

there is growing interest in determining the effect of sirtuins in mammal cells. Like their yeast homologs, the mammalian sirtuins (SIRT1-7) were originally described as deacetylase proteins (class III HDAC) requiring NAD+ as a cofactor to deacetylate substrates ranging from histones to transcriptional regulators (Blander et al, 2004). Based in the phylogenetic analysis mammalian sirtuins can be divided into four classes: SIRT1-SIRT3 belongs to class I, SIRT4 to class II, SIRT5 to class III and SIRT6 and SIRT7 to class IV (Frye et al, 2000). Also, it is described that mammalian sirtuins have diverse cellular localization and target multiple substrates, consequently affecting a broad range of cellular functions. Specifically, SIRT6 is in the nucleus where promotes DNA repair and protect against genomic instability (Michishita et al, 2008). Moreover, it's described that SIRT6 could modulate telomeric chromatin and regulates genomic stability on the cellular level and ageing-associated pathologies at the organismal level (Mostoslavsky et al, 2006). On the other hand, a recent paper has demonstrated that SIRT6 binds to the NF-κB subunit RelA and attenuates Nf-κB signalling by modifying chromatin at NF-κB target genes (Kawahara et al, 2009). NF-κB family is considered an emerging modulator of ageing-related pathways in mammals that controls the activity of genes involved in apoptosis, cell senescence, inflammation, and immunity.

Ageing and hypertension represent two major independent risk factors for cardiovascular disease. Many of the cardiovascular complications associated with both ageing and hypertension are attributable, at least in part, to endothelial dysfunction. The pathophysiology of endothelial dysfunction is complex and involves multiple mechanisms. One potential trigger for endothelial dysfunction is inflammation (Clapp et al, 2004) and recently it has been increasingly linked to cellular senescence process (Erusalimsky, 2009). The aim of this study was to investigate whether SIRT6 has an effect in endothelial cells senescence and dysfunction and the model of action. In this presentation we will show that SIRT6 is expressed in endothelial cells, mRNA expression (n=3-6) analysis of SIRT1 and SIRT6 was measured by quantitative polymerase chain reaction using Taqman probes. SIRT6 expression was higher in differentiated endothelial cells compared to hematopoietic progenitor cells and presented similar levels to SIRT1 in mature endothelial cells. Furthermore, comparing early and late passages of endothelial cells showed a decreased of SIRT6 expression due to replicative senescence, in both, mRNA (n=3) and protein levels (n=3) measured by western blot. SIRT6 depletion by RNA interference induced a decrease in endothelial cells proliferation quantified by BrdU immunofluorescence assay (n=4), increased senescence-associated-b-galactosidase positive cells (n=4) and diminished ability of the cells to form tubule networks on Matrigel coating (n=5-6), all features of cell senescence. Consistent with this notion, SIRT6-depleted cells presented higher levels of intercellular-adhesion-molecule-1 (ICAM-1) in both, mRNA (n=9) and protein levels (n=3) analysed by flow cytometry. Also showed an increase of PAI-1 mRNA levels (n=9) and lower levels of eNOS mRNA (n=9) and protein (n=3). On the other hand, we examined the accumulation of γH2AX foci by immunofluorescence in SIRT6 depleted cell (n=3). We detected a significant increase in γH2AX foci and in the co-localization with TRF-1, meaning that SIRT6 attenuates DNA damage and telomere dysfunction. Finally, we studied the downstream mechanism by which senescence is induced in SIRT6 depleted cells, higher levels of p21, a cyclin-dependent kinase, was present in SIRT6-depleted cells compared to controls (n=4). These data demonstrate that SIRT6 is highly expressed in endothelial cells where it confers protection from both genomic DNA damage and telomere dysfunction. Besides, our finding that SIRT6 depletion induces senescent phenotype suggests that increasing the activity of this sirtuin may be a relevant approach to delay vascular ageing.

Endothelial cell senescence: molecules and mechanisms

P. Jansen-Dürr

Research Institute for Biomedical Aging Research, University of Innsbruck, Innsbruck, Austria

The free radical theory of aging suggests that reactive oxygen species (ROS) are a driving force of the aging process. In many postmitotic tissues with high mitochondrial activity, the mitochondria are considered as main sources of ROS, which arise as by-products of oxidative metabolism. However, in recent years it has been shown that depending on the tissue type also nonmitochondrial enzymes, such as NADPH oxidases and other oxidative enzymes, can contribute significantly to the cellular load of ROS. The emerging picture suggests that various sources of ROS contribute in a different way to aging phenotypes in various tissues. Using senescence of human endothelial cells as a model system, we reported previously that endogenous levels of NADPH oxidase Nox4 are major drivers of human endothelial cell senescence, by inducing a DNA damage response (Lener et al., 2009). We have addressed molecular mechanisms by which Nox4 may induce DNA damage and found an unanticipated link to the mitochondria, which seem to act as important signal amplifiers. We also found that the hydrogen sulphide (H_2S)-producing enzyme cystathione beta-synthase (CBS) regulates senescence of human endothelial cells (Albertini et al., 2012); the role of H_2S in cellular senescence will be discussed.

Endothelial senescence in smokers and COPD patients

K.E. Paschalaki[1,2], R.D. Starke[2], Y. Hu[4], N. Mercado[1], A. Margariti[4], V.G. Gorgoulis[3], P.J. Barnes[1] and A.M. Randi[2]

[1]Airway Disease Section, National Heart & Lung Institute, Imperial College London, London, UK, [2]Vascular Sciences, National Heart and Lung Institute, Imperial College London, London, UK, [3]Department of Histology and Embryology, University of Athens, Athens, Greece and [4]Cardiovascular Division, King's College London, London, UK

Introduction: Cardiovascular disease (CVD) is a major cause of death in smokers, particularly in patients with chronic obstructive pulmonary disease (COPD), an obstructive lung inflammatory disorder affecting approximately 20% of smokers. Even though numerous studies describe evidence of endothelial dysfunction in young healthy smokers and COPD patients, the molecular pathways that link cigarette smoke and CVD remain unclear.

Increased DNA damage and cellular senescence have been recognized as important contributors to CVD. DNA damage, caused by factors such as oxidative stress, activates ataxia-telangiectasia mutated (ATM) kinase, a key player in the DNA damage response (DDR), and results in cell cycle arrest, senescence or apoptosis. Senescent vascular cells exhibit dysfunctional characteristics and have been shown to contribute to accelerating vascular aging and atherosclerosis.

Circulating endothelial progenitor cells (EPC) are required for endothelial homeostasis, and their dysfunction also contributes to CVD. Blood outgrowth endothelial cells (BOEC, also called endothelial colony forming cells - ECFC), are a well characterized endothelial cell population with robust clonal proliferative potential and ability to form de novo vessels *in vivo*. This population has recently attracted considerable interest as a potential cell-based therapy for vascular regeneration, and as a tool to study endothelial dysfunction in patients.

Our aim was to investigate whether EPC from smokers and COPD patients are dysfunctional due to increased DNA damage imposed by cigarette smoke-oxidative stress, which could contribute to the development of CVD, and to elucidate the pathways involved in this process.

Methods: To investigate EPC dysfunction in smokers, we isolated and expanded BOEC from peripheral blood samples of healthy non-smokers, healthy smokers and COPD patients. The mononuclear fraction was placed in culture in the presence of endothelial growth factors and BOEC colonies appeared between days 7 and 24. BOEC colonies were expanded and used at passages 4 to 6 for all experiments. Endothelial senescence was measured by senescence-associated β-galactosidase (SA-β-Gal) activity. Expression of sirtuin (SIRT)-1, p16, p21, γ-H2AX and 53BP1 were measured by Western blotting and/or immunofluorescence confocal microscopy. SIRT1 activity was measured using a SIRT1 fluorescent activity assay kit. To investigate angiogenesis *in vivo*, BOEC were labelled with Vybrant DiI Cell-Labelling Solution, mixed with Matrigel and injected subcutaneously into the back of NOD.CB17-Prkdcscid/NcrCrl mice. Seven days later, the mice were sacrificed and the plugs were harvested and cryosectioned.

Results: *In vitro*, BOEC from smokers and COPD patients showed increased DNA double-strand breaks (measured by γ-H2AX, 53BP1) and senescence (senescence associated-β-galactosidase activity, p16 and p21 levels) compared to non-smokers. Senescence negatively correlated with expression and activity of sirtuin-1 (SIRT1), a protein deacetylase that inhibits DNA damage and cellular senescence. Inhibition of DNA damage response by silencing of ATM kinase resulted in up-regulation of SIRT1 expression and decreased senescence. Interestingly, treatment of BOEC from COPD patients with the SIRT1 activator resveratrol or a selective ATM inhibitor rescued the senescent phenotype. Using the *in vivo* Matrigel plug assay, BOEC from COPD patients displayed reduced ability to form capillary-like structures and increased DNA damage, senescence and apoptosis (measured by 53BP1, p16, TUNEL and cleaved-caspase 3 staining) compared to non-smokers.

Conclusions: This study provides evidence of epigenetic alterations in endothelial progenitors from smokers, linked to cigarette smoke-oxidative stress, namely reduced SIRT1 expression via activation of the DNA damage response / ATM pathway. We demonstrated that progenitor cells of the endothelial lineage in smokers and COPD patients show reduced angiogenesis *in vivo* and display increased DNA damage and senescence, associated with reduced SIRT1 expression. These defects may contribute to endothelial dysfunction and cardiovascular events in smokers and COPD patients and could potentially constitute therapeutic targets for intervention.

Smooth muscle cell senescence in atherosclerosis

M. Bennett

Division of Cardiovascular Medicine, University of Cambridge, Cambridge, UK

Background: Despite the historical focus on cell proliferation in atherosclerosis, advanced plaques are characterized by vascular smooth muscle cell (VSMC) senescence, apoptosis, persistent DNA damage and activation of the DNA damage response (DDR).

Methods and Results: Using a series of mouse models, we find that VSMC senescence is regulated by DNA damage and repair, and promotes features of vulnerable plaques, including reduced fibrous cap thickness and expansion of the necrotic core. VSMC senescence may also promote medial degeneration, aneurysm formation and ongoing inflammation. We show that oxidative stress regulates both telomere dependent and independent senescence, and senescence is inhibited by DDR proteins and sirtuins. Mitochondrial DNA damage occurs early in atherosclerosis, and can also promote both VSMC senescence and atherosclerosis.

Conclusions: VSMC senescence directly promotes atherosclerosis and medial degeneration, mediated through nuclear and mitochondrial DNA damage

Reactive oxygen species signalling in microvascular permeability

P. Fraser

BHF Centre of Research Excellence, Cardiovascular Division, King's College London, London, UK

The brain endothelium constitutes a barrier to the passive movement of substances from the blood into the cerebral microenvironment, and disruption of this barrier after a stroke or trauma has potentially fatal consequences. Reactive oxygen species (ROS), which are formed during these cerebrovascular accidents, have a key role in this disruption. ROS are formed constitutively by mitochondria and also by the activation of cell receptors that transduce signals from inflammatory mediators, e.g., activated phospholipase A_2 forms arachidonic acid that interacts with cyclooxygenase and lipoxygenase to generate ROS. Endothelial NADPH oxidase, activated by cytokines, also contributes to ROS. There is a surge in ROS following reperfusion after cerebral ischemia and the interaction of the signaling pathways plays a role in this. ROS are transiently generated during reperfusion following cerebrovascular ischaemia, which results in the initial disruption of the blood-brain barrier. This allows plasma proteins into the brain substance that leads to gliosis and subsequent destruction of brain tissue. We have investigated the source of this reperfusion injury-generated ROS in single venular capillaries on the cortical surface of the brain in young anaesthetized rats. The permeability to sulforhodamine dye (588 Da) of single venular capillaries of rats (anaesthetized with pentobarbitone: 60 $mg.kg^{-1}$ ip, an overdose of which was administered to kill humanely) was measured by the occlusion technique. Cerebral ischaemia-reperfusion was instigated by infusing into the internal carotid artery 40 μm starch microspheres that subsequently dissolve due to the action of plasma amylase. This produced a blockage of the middle cerebral artery territory and we found that the permeability of previously tight venules increased with the duration of the ischaemia. This permeability increase was sensitive to blocking the bradykinin B2 receptor, but was an order of magnitude greater than the maximum permeability response to acutely applied bradykinin. Acutely applied bradykinin itself results in a free radical scavenger sensitive and calcium entry dependent permeability response. The source of this ROS was shown to be both cyclooxygenase and lipoxygenase activated by arachidonic acid released by phospholipase A_2 activated in response to the applied bradykinin. Prolonged application of bradykinin did not itself increase the response, but permeability did increase after 30 min, and this was blocked by inhibiting the interleukin-1 receptor. We also found that interleukin-1β (IL-1β) application before applying bradykinin resulted in a large potentiation of the response. Furthermore, the early component of the potentiated response was shown to be sensitive to inhibiting NOX-2 assembly (Fig. 1). The vascular permeability response to the starch microsphere injection was also measured in the whole of the affected hemisphere by using escape of horseradish peroxidase (HRP) into the tissue. 50 μm thick sections were incubated with diaminobenzidine (DAB) and the rate of development of the reaction product was used to calculate the concentration of HRP in the tissue by comparison with brains soaked in HRP standard solutions. The PS product was calculated after 30 minutes reperfusion from the time averaged plasma HRP concentration according to the Crone-Renkin equation. PS increase depended on the duration of the blockage of the circulation and was greatest on the pial surface and radial veins draining the cortex. These experiments confirmed that the permeability increase on reperfusion lasted for less than 1h, and could be much reduced by preventing the formation of the hydroxyl radical by treating the animal with desferrioxamine which chelates the ferrous ion, so preventing the Fenton reaction.

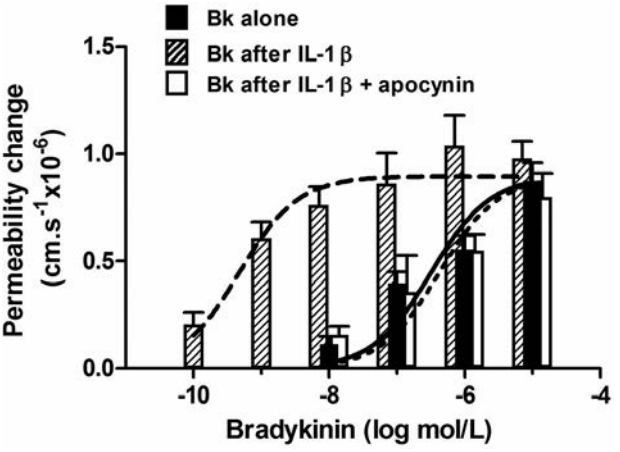

Figure1. Concentration–response curves for bradykinin before and after treatment with IL-1β in the presence of cycloheximide to prevent protein synthesis thought to be responsible for the later permeability increase. Apocynin co-applied with IL-1β, and removed with it, completely blocked the potentiation.

Regulation of endothelial barrier by Rho GTPases

M. Aslam[2,1], C. Hamm[2] and D. Guenduez[2]

[1]Institute of Physiology, Justus Liebig University, Giessen, Germany and [2]Cardiology and Angiology, Justus Liebig University, Giessen, Germany

Introduction: Endothelial barrier dysfunction is associated with many types of vascular diseases (e.g. atherosclerosis, inflammation and ischemia/reperfusion). Endothelial barrier function is mainly regulated by cell-cell adhesions and endothelial contractile machinery. Rho family of GTPases particularly RhoA and Rac1 are the main regulators of both endothelial cell-cell

adhesions and contractile machinery. The activity of Rho GTPases is regulated by different mechanisms including by post-translational prenylation. Prenylation of both RhoA and Rac1 is regulated by farnesyltransferase and geranylgeranyltransferase, and dysregulation of their activity may influence the activity of RhoA and Rac1. In the present study, the effect of RhoA and Rac1 prenylation on endothelial permeability was analysed.
Methods: The study was performed on isolated human umbilical vein endothelial cells (HUVECs). Endothelial barrier function was analysed by measuring flux of labeled albumin through HUVEC monolayers. RhoA and Rac1 activity was measured by pulldown assay. Thrombin was used as an inflammatory mediator.
Results and Conclusion:
In this presentation, we will present the data showing how interfering with the activities of farnesyltransferase and geranylgeranyltransferase can differentially affect the activities of Rho GTPases and thus influence endothelial permeability both positively and negatively. Moreover, the data on the influence of statins, which also inhibit protein prenylation, on Rho GTPases and thus endothelial barrier function will be discussed.

SA22

Role of calcium signaling on cyclic nucleotide regulation of vascular permeability

D. Mehta

Pharmacology, University of Illinois, Chicago, IL, USA

The vascular endothelium interfacing between the blood and vessel wall has the vital functions of regulating tissue fluid balance and supplying the essential nutrients needed for the survival of the organism. It is known that loss of this function results in tissue inflammation, the hallmark of inflammatory diseases such as the Acute Respiratory Distress Syndrome. Dynamic interaction between adherens junctions and cell-matrix attachments plays a primary role in regulating endothelial permeability. However, counter-adhesive forces generated by actinomysin molecular motors activated upon inflammatory mediators such as thrombin, bradykinin, histamine, VEGF, and others upon binding to their receptors, disrupt the organization of adherens junctions and cell-matrix complexes, thereby opening the junctional barrier.
An increase in cytosolic Ca2+ has been established as the initial pivotal signal that precedes endothelial cell shape change and opening of adherens junctions resulting in barrier dysfunction. Following cell stimulation with inflammatory mediators, an increase in cytosolic Ca2+ concentration is apparent. There is an initial transient peak as the result of Ca2+ release from endoplasmic reticulum (ER) stores, which is followed by more sustained response secondary to Ca2+ entry via plasmalemma channels. Ca2+ entry refills ER stores and sustains Ca2+ signaling. Proteins of the transient receptor channel (TRPC) family are non-selective cation channels present in endothelial cells that increase intracellular Ca2+, and play an important role in regulating actin-myosin motor activity and endothelial barrier function. Human pulmonary endothelial cells highly expressed TRPC1 and TRPC6, whereas TRPC3, TRPC4, and TRPC7 are expressed only weakly. TRPC1, TRPC4, and TRPC5 are activated by depletion of ER stores, and are therefore called store-operated channels (SOCs), whereas TRPC3 and TRPC6 are activated independently of store depletion, and are referred to as receptor-operated channels (ROC). SOCs and ROCs provide the primary structures by which Ca2+ enters endothelial cells. Both SOC and ROC have been shown to induced actin-myosin induced endothelial cell contraction and thereby endothelial permeability.
In contrast to Ca2+, an increase in the concentration of cAMP is known to stengthen endothelial barrier function such that it prevents increased permeability in response to known permeability-increasing mediators in endothelial cells and intact microvessels. Evidence indicates that increased levels of cAMP can be endothelial barrier protective through the cAMP-dependent kinase, PKA as well as modulation of adherens junctions and cell-matrix attachemnets. Cyclic AMP response element binding (CREB) protein is a nuclear transcriptional factor that regulates several cellular functions such as inflammation, cell proliferation, differentiation, adaptation and survival. We have shown that CREB plays a pivotal role in regulating endothelial barrier function by restricting endothelial contraction through regulating the expression of p190RhoGAP. These findings indicate that TRPC and cAMP-mediated signaling mechanisms must intersect with each other to regulate endothelial permeability. My objectives in this presentation will be to discuss the data from genetic, physiological, cellular, and morphological studies whether TRPC- and cAMP-mediated signaling intersects and how this intersection plays a role in regulating endothelial barrier function.

SA23

Sphingosine-1-phosphate regulation of endothelial cytoskeleton

J.G. Garcia

Office of the Vice President for Health Affairs, University of Illinois Hospital and Health Sciences System, Chicago, IL, USA

Effective therapies to limit the profound vascular leakage in inflammatory injury are severely limited. Our early translational investigations first suggested sphingosine 1-phosphate (S1P), a multifunctional lipid mediator and angiogenic factor, as an effective therapy for reducing vascular leakage in inflammatory lung injury. We have shown that S1P rapidly stimulates a Rac GTPase-driven signaling cascade leading to reorganization of the vascular endothelial cell cytoskeleton and enhanced junctional integrity, biophysical events which ultimately strengthen the EC barrier and decrease vascular permeability. Importantly, S1P administration to mice with endotoxin (LPS)-induced lung injury or to dogs in a lung injury model induced by intrabronchial LPS instillation, markedly improves oxygenation and reduces alveolar edema formation. As S1P is found in nano-micromolar quantities in plasma, the expres-

sion and dynamic responses of G-protein-coupled S1P receptors (S1PRs) serve to coordinate cellular responses to S1P. S1PR1, S1PR2, and S1PR3 are highly expressed in lung vascular endothelium, however, only ligation of S1PR1 reduces murine lung vascular permeability in response to LPS, ischemia/reperfusion, ventilator–induced injury and ionizing radiation. Furthermore, S1PR1 is critical to hepatocyte growth factor-, hyaluronan- and activated protein C-mediated EC barrier enhancement via S1PR1 transactivation. In contrast, ligation of S1PR3 induces Rho GTPase signaling to the cytoskeleton and increased lung permeability. We recently investigated the role of specific S1P/S1PR responses in inflammatory lung injury including dose- and delivery route-dependent (intratracheal vs intravenous) effects of S1P and selective S1PR receptor agonists and antagonists on vascular leakage in wild type and genetically-engineered mice in relevant murine models of inflammatory lung injury. We determined that direct intratracheal (IT) or intravenous (IV) administration of S1P, or a selective S1PR1 agonist (SEW- 2871) produces highly concentration-dependent barrier-regulatory responses in the murine lung. IT or IV administration of S1P or SEW-2871 at <0.3 mg/kg was protective against LPS-induced murine lung inflammation and permeability, however, IT delivery of S1P at 0.5 mg/kg (2hrs) resulted in significant alveolar-capillary barrier disruption (42% increase in BAL inflammatory protein) and produced rapid lethality when delivered at 2 mg/kg. Despite greater S1PR1 selectivity, IT-delivered SEW-2871 at 0.5 mg/kg also resulted in significant alveolar-capillary barrier disruption but was not lethal at 2 mg/kg. Consistent with S1PR1 regulation of alveolar/vascular barrier function, wild type mice pretreated with a S1PR1 antagonist, SB-649146, or S1PR1+/- mice exhibited loss of S1P/SEW-2871-mediated barrier protection following LPS challenge. Finally, our gene resequencing studies identified novel SNPs in genes involved in sphingolipid metabolism, S1P-mediated vascular signaling, and S1P-mediated barrier regulation which are potentially involved in susceptibility to ALI. These studies, which underscore the potential therapeutic effect of highly selective S1PR1 receptor agonists in reducing inflammatory lung injury, highlight the critical role of S1P delivery route, S1PR1 agonist concentration, and S1PR1 expression in target tissues.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Brown and white adipose tissues: functional significances

J. Nedergaard and B. Cannon

The Wenner-Gren Institute, Stockholm, Sweden

Whereas we earlier thought about the existence of just two different adipose tissues – heat-producing brown and energy-storing white – we now see a much broader spectrum of tissues and cells; - and whereas we earlier thought that brown and white adipose tissues were closely related tissues, as the names imply, we now realize that brown adipose tissue is really developmentally a kind of muscle tissue – and although we do not really know the developmental origin of white adipose tissue, it is clearly not of muscle origin. These different developmental backgrounds are highly reflected in the character of metabolism in the tissues. To this should be added that certain cells (presently called brite or beige) within certain white adipose tissue depots may be able to express the (earlier considered) unique protein of brown adipose tissue: UCP1. The functional significances of the tissues for thermogenesis is strongly related to their ability to express sufficiently high levels of UCP1 to allow them to play a role in systemic metabolism. Whereas the issue of functional significance of the brown and white adipose tissue was earlier an issue mainly of academic interest – as it was thought that brown adipose tissue was not found in adult humans – the present understanding that brown fat exists and is active in adult humans has lifted the issue of the functional significance of the brown adipose tissue to being an enticing and possibly important issue in human metabolic research.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA25

Regulation of brown adipose tissue development: Progenitors, BMPs and beyond

T.J. Schulz

Adipocyte Development, German Institute of Human Nutrition, Nuthetal, Germany and Integrative Physiology and Metabolism, Joslin Diabetes Center, Boston, MA, USA

Obesity develops due to an imbalance of increased energy intake over decreased energy expenditure. A sedentary lifestyle in combination with readily available, energy-dense food sources have led to a pandemic spread of obesity in modern societies that represents a significant challenge to medical care systems. Excess calories from food are stored as triglycerides within the white adipose tissue (WAT), exacerbating a number of diseases associated with pathological overweight, such as diabetes, cardiovascular complications, and dyslipidaemias. Brown adipose tissue (BAT) is a specialized fat tissue that is dedicated to body temperature regulation. Due to its remarkable capacity for thermogenesis and its demonstrated presence in adult humans, BAT holds great promise for the treatment of obesity and the metabolic syndrome [1]. Two distinct types of brown fat cells have recently been described in mammalians: the constitutive or classical BAT (cBAT), which is of embryonic origin and anatomically located in the interscapular region of mice; and the so called recruitable BAT (rBAT), that has alternatively been termed brite (brown-in-white) or beige fat, due to its predominant anatomical distribution within WAT. While a common set of progenitor cells may give rise to white adipocytes and rBAT (within WAT), cBAT derives from a developmental lineage that is more closely related to skeletal muscle. Accordingly, recent findings have not only established that cBAT-progenitors are marked by a myogenic gene expression signature, but also that myogenic transcription factors, such as Myf5 and Pax7, are expressed in a common lineage of embryonic progenitors that give rise to cBAT in addition to skeletal muscle [2-4].

Morphogens have been implicated as instructive signals in the lineage determination of brown adipogenic progenitors. In this line, we were recently able to show that bone morphogenetic protein (BMP)-7 regulates the formation of brown adipocytes in multipotent progenitor cells, whereas loss of BMP7 resulted in a marked paucity of embryonic cBAT [5]. Interestingly, emerging evidence has also implicated BMP7 and BMP8b in the control of thermogenic capacity of mature BAT, altogether highlighting the central role of this pathway in brown fat physiology.

Taking advantage of these observations, we generated a knockout mouse model with conditional ablation of the type 1A BMP

receptor, BMPR1A, which functions as a major receptor for BMP7. Loss of BMPR1A in cells of the common muscle/cBAT-lineage severely impairs the formation of cBAT but not skeletal muscle during embryogenesis, thereby leading to reduced body temperature in new-born mice. Adult knockout mice, however, display an unexpected normalization of body temperature and overall thermogenic capacity. Importantly, knockouts are able to resume normal body temperature following prolonged exposure to cold, indicating that compensatory mechanisms are in place to counter the defect in thermoregulation induced by cBAT-paucity. Indeed, knockout mice show a greater propensity to recruit brown adipocytes within their classical WAT-depots, a process that is associated with increased sympathetic input to WAT. This previously unknown compensatory mechanism, aimed at restoring total brown-fat-mediated thermogenic capacity in the body, is sufficient to maintain normal temperature homeostasis and resistance to diet-induced obesity. These data suggest an important physiological cross-talk between constitutive and recruitable brown adipocytes involving cBAT-to-brain and brain-to-WAT communications and that is at least partially mediated by the sympathetic nervous system. This regulatory mechanism of body temperature may participate in the control of energy balance and metabolic disease and could provide a novel target for therapeutic approaches aimed at shifting the energy balance to a beneficial proportion [6].

Turning off the furnace: downregulation of BAT function during lactation in mice

E. Krol

Institute of Biological and Environmental Sciences, University of Aberdeen, Aberdeen, UK

It has been proposed that the performance of lactating animals is limited by the capacity of the female to dissipate body heat – the heat dissipation limit (HDL) theory (Król and Speakman 2003, Speakman and Król 2010). This theory predicts that milk production might be constrained not by intrinsic properties of the mammary glands but rather by competitive heat production such as thermogenesis in brown adipose tissue (BAT). To test this prediction, we measured the expression of genes linked to thermogenesis in BAT of lactating laboratory mice. The applicability of BAT gene expression to reflect thermogenic activity of BAT was confirmed by a positive relationship between expression levels of several BAT genes (summarised by the first principal component following principal component analysis) and daily energy expenditure in virgin mice. Milk production at peak lactation was strongly and negatively associated with the expression of thermogenic genes in BAT (Fig. 1). Downregulation of these genes during lactation was correlated with low levels of circulating leptin and high levels of circulating prolactin (Fig. 2). We used path analysis to further examine associations between hormone levels, BAT activity (reflected by the PC1 scores) and milk production in lactating mice. Low levels of circulating leptin were correlated with and may contribute to the increase in milk production by reducing BAT activity and by BAT-independent mechanisms. High levels of circulating prolactin were correlated with increased milk production via associations with the activity of BAT rather than by BAT-independent mechanisms, but the relationships with prolactin were weaker than those with leptin. Our results are consistent with the prediction of the HDL theory that downregulation of BAT thermogenesis reduces competitive heat production, permitting greater production of lactogenic heat within the overall heat dissipation capacity limit. However, we cannot discount an alternative explanation that the causality in the associations is the reverse, i.e. that greater milk production, directly via thermogenic mechanisms alone (Cannon and Nedergaard 2004) or via endocrine and physiological processes, reduces BAT activity. The highly coordinated downregulation of thermogenic genes in BAT during lactation provides a new model system to investigate molecular pathways involved in switching on and off BAT activity and function.

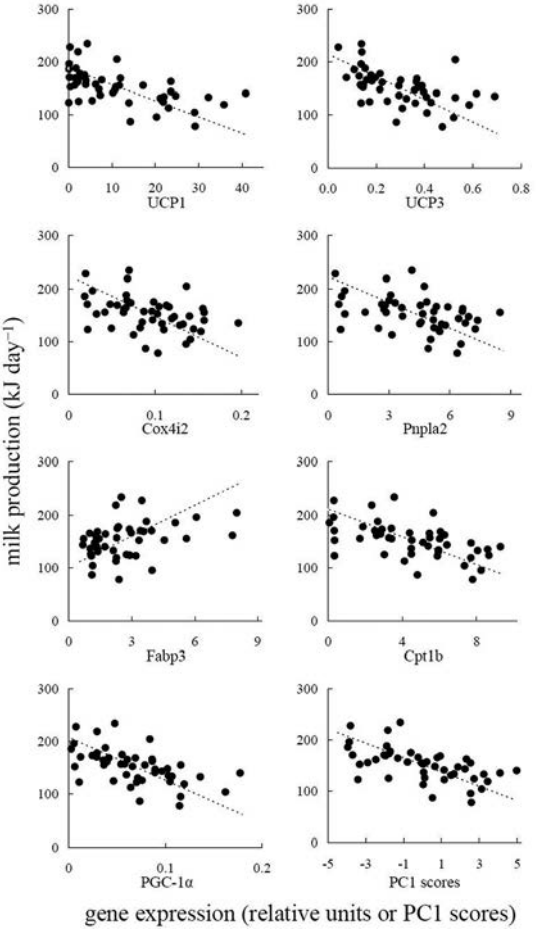

Fig. 1. Milk production plotted against the expression of several genes in brown adipose tissue (BAT) of lactating mice (N=47). Gene expression is normalized against the expression of housekeeping genes and presented in relative units. PC1 scores summarise the expression levels of thermogenic genes in BAT of lactating mice. All associations are significant (P<0.05) and fitted with the lines that represent reduced major axis regressions.

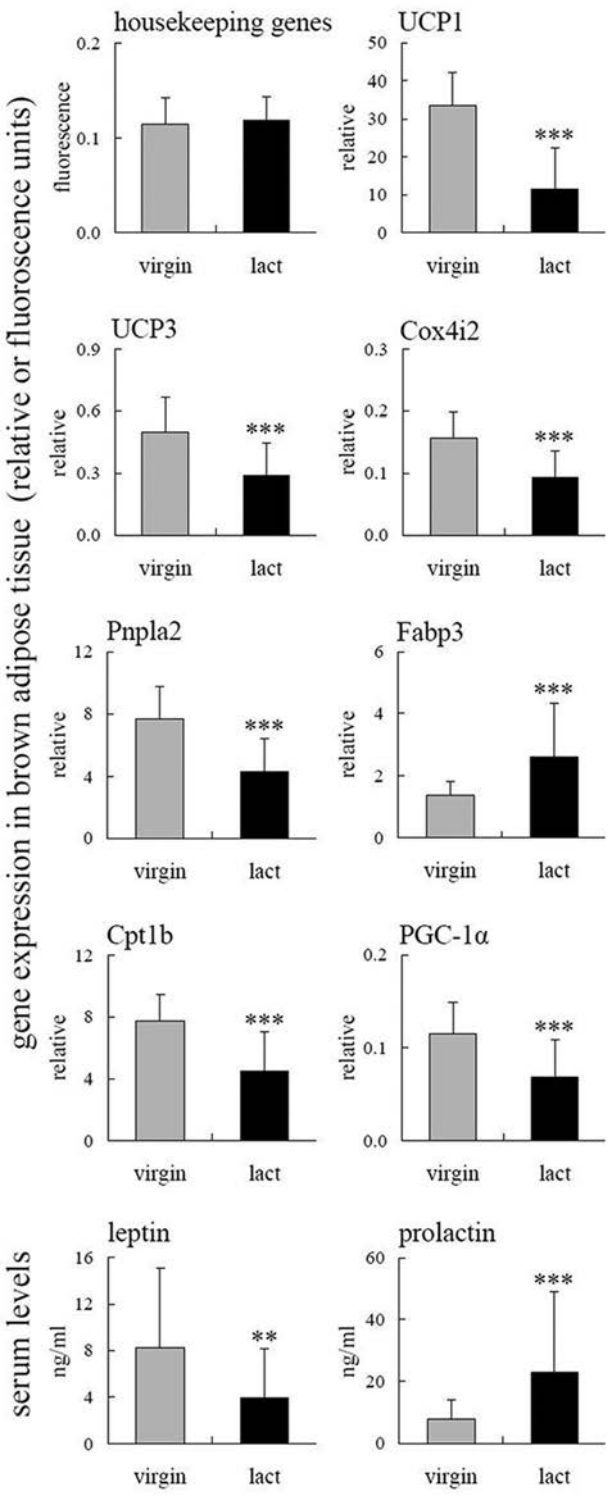

Fig. 2. Expression of genes in brown adipose tissue and corresponding levels of circulating leptin and prolactin in lactating (N=47) and virgin female (N=16) mice. Expression of housekeeping genes (geometric mean expression of β-actin and Rpl13a) is in arbitrary fluorescence units; expression of thermogenic genes is normalized against the expression of housekeeping genes and presented in relative units. Bars represent mean + 1 standard deviation. **P<0.01, ***P<0.001.

Browning of adipose organ

S. Cinti

University of Ancona, Via Tronto 10a 60020 Ancona, Italy

Most of white and brown adipocytes, in spite of their well known different functions: i.e. storing energy (white) and thermogenesis (brown), are contained together in visceral and subcutaneous depots (adipose organ) in all mammals including humans. A growing body of evidence suggests that the reason for this anatomical mixture could reside in the fact that adipocytes have peculiar plastic properties allowing them to convert directly each other under appropriate stimuli. Under chronic cold exposure white convert into brown to support the need for thermogenesis and under obesogenic diet brown convert into white to satisfy the need of energy storing.
We recently showed that both white and brown adipocytes originate from endothelium of capillaries in adipose tissues. Differentiation imply a transformation of poorly differentiate cells that progressively assume structural and functional properties determining a specific phenotype. Electron microscopy defines specific steps of differentiation for white and brown adipocytes development. White and brown adipogenesis can occur in adipose organ of adult mammals under specific environmental requirements such as obesity (whitening) or cold adaptation (browning). The cytological modifications during whitening and browning of adipose organ are quite different from those of white or brown ontogenesis and suggest a direct conversion of mature adipocytes into a different phenotype (transdifferentiation). Morphometric and BrdU data obtained from the analysis of most depots of adult adipose organ in different strains of mice confirmed that this plasticity is mainly due to transdifferentiation. By lineage tracing and graft experiments we also showed that white adipocytes are able to reversibly transdifferentiate into milk-secreting epithelial cells in mammary glands of pregnant and lactating mice. Thus, transdifferentiation is a plastic phenomenon that can occur physiologically in the adipose organ of adult mammals with important implications for the therapeutic control of widely diffuse pathologies because the brown phenotype of the adipose organ is associated with obesity resistance and drugs inducing the brown phenotype curb obesity and T2 diabetes.

CFTR activation by specific regions of the R domain

J. Chen[1] and M.J. Welsh[2]

[1]Department of Physiology, University of Hong Kong, Hong Kong, China and [2]Internal Medicine, University of Iowa, Iowa City, IA, USA

Cystic fibrosis transmembrane conductance regulator (CFTR) is an anion channel activated by PKA-dependent phosphorylation on its regulatory domain (R domain). Previous studies have demonstrated that the R domain controls phosphoryla-

tion-dependent CFTR activation by multiple effects including inhibition and stimulation on channel activity. However, it is unclear whether specific regions in the R domain are account for these mechanisms controlling CFTR activation. To test this hypothesis by screening the function of different R domain regions, we constructed a variety of R domain deletions over the region from residue 708 to 835 in CFTR. We studied the single-channel activity and PKA-independent constitutive Cl^- currents of these CFTR constructs. Our data indicate that deleting region 784-835 generated little constitutive Cl^- currents in the presence of 1 mM ATP alone, but reduced greatly CFTR channel activity after PKA phosphorylation. Further studies on small deletions in this region suggest that whole region 784-835 regulates the closing rate of the CFTR channel, whereas region 829-835 also modulates the channel opening rate. Therefore, the C-terminal part of the R domain is required for normal CFTR activity. Conversely, deletions of region 708-759 and region 760-783 had small effects on channel activity. Moreover, deleting region 760-783 or subregions 760-769 and 770-776 produced large constitutive Cl^- currents. These data suggest that region 760-776 may form an inhibitory motif that prevents CFTR activation. Taken together, our data suggest that the small R domain regions in different locations may form functional motifs that either inhibit or stimulate the channel activity of CFTR.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

3D structural models of CFTR

J. Mornon[1], B. Hoffmann[1], P. Lehn[2] and I. Callebaut[1]

[1]UMR7590, CNRS, Université Pierre et Marie Curie, Paris, France and [2]INSERM U1078, Université de Bretagne Occidentale, Brest, France

Cystic Fibrosis Transmembrane conductance Regulator (CFTR) is a chloride channel belonging to the large family of ABC exporters. The onset of the first experimental 3D structure, at atomic resolution, of a member of the ABC exporter family has permitted to perform homology modeling of the whole 3D structure (except for the regulatory R domain, which appears less structured). Presently, seven experimental structures of ABC exporters are known, in outward- and inward-facing conformations, having allowed to propose several models of the open and closed states of the ion channel, respectively.
These models, together with the results coming from several molecular dynamics studies, have been widely used to better understand the molecular basis of the CFTR functions, which intimately depend on the intricate interactions between the different subunits.
Recently, based on the improved knowledge we acquired from the experimental 3D structures, we made a new model of the open form of the CFTR channel, always based on the Sav1866 structure but refined in the Membrane Spanning Domains, which share very low levels of sequence identity with the ABC exporters templates. Moreover, we made a comprehensive analysis of the available 3D structures of ABC exporters, in order to define the conformational transition pathway followed between outward- and inward-facing conformations. This provide a new vision of the CFTR pore, both for the open and closed forms, the latter one being characterized by a more limited dissociation of the two Nucleotide-Binding Domains (NBDs) than for classical ABC transporters.
Altogether, the whole set of models of the 3D structure of human CFTR in different conformations open the door to a search of specific molecules, which may be able to fix the assembly of the different domains of the protein, a major cause of the low ability of CFTR to reach and remain at the membrane.

CFTR's degenerate nucleotide binding site 1 probably moves during channel gating

L. Csanády[2], C. Mihályi[2], A. Szollosi[2], B. Töröcsik[2] and P. Vergani[1]

[1]Neuroscience, Physiology and Pharmacology, University College London, London, UK and [2]Medical Biochemistry, Semmelweis University, Budapest, Hungary

The CFTR ion channel belongs to the ATP binding cassette (ABC) protein superfamily. All ABC proteins share a similar domain organization with a "core" functional unit comprising two cytosolic nucleotide binding domains (NBDs) and two transmembrane domains (TMDs) (Fig. 1A). NBDs bind and hydrolyze ATP. Structurally they comprise a RecA-like subdomain ("head"), and a helical subdomain ("tail"). In the presence of ATP, NBDs can associate to form a tight "head-to-tail" dimer with two composite ATP binding sites at the interface (Fig. 1B). The ATP molecules provide crucial molecular contacts that stabilize the dimer. It is generally believed that NBD dimerization - driven by ATP binding - and dimer disengagement - following ATP hydrolysis - couple ATPase cycles to functionally important conformational changes in the TMDs. Most ABC proteins are transporters while CFTR, alone, is an ion channel. However, it was proposed that CFTR gating is "driven" by ATP binding and hydrolysis employing the molecular mechanisms used by transporters: ATP binds to NBD1 and NBD2 which associate to form an intramolecular "dimer" with composite sites 1 and 2 buried at the interface; ATP at site 2 is then hydrolyzed, triggering dimer dissociation; NBD dimer formation and dissociation are sensed by the TMDs where they result in opening and closing, respectively, of the pore (Fig. 1C).
In CFTR, consensus motifs involved in ATP binding and hydrolysis are conserved only in site 2. In site 1, non-conservative substitutions at key residues result in tight ATP binding, but no efficient hydrolysis. Non-canonical substitutions in the same key positions, presumably resulting in reduced or absent hydrolysis at one composite site, are also seen in other important human (e.g. TAP1/TAP2 and SUR) as well as in numerous yeast and prokaryotic transporters. The latter group includes TM287/288, a heterodimeric transporter whose high resolution structure has been very recently solved [1]. At site 1 in this crystal, an ATP molecule is bound and NBDs maintain contact but dimer interface is largely solvent accessible. Early biochemical studies revealed that ATP remains bound, unhydrolyzed, at CFTR's site 1 for periods of time much longer than a channel gating cycle (~1 s). This finding was confirmed in a recent functional study [2]. The high-affinity ATP analogue N6-(2-phenylethyl)-ATP (P-ATP) was found to speed up opening and to slow down closing of CFTR channels. The onset of these two effects, following sudden replacement of ATP with P-ATP,

followed distinct time courses. Whereas the effect on opening rate appeared immediately, likely reflecting P-ATP binding to the rapid-turnover site 2, the onset of slowed closure was delayed by 30-50 s, consistent with an action of P-ATP at slow-turnover degenerate site 1. Furthermore, because nucleotide exchange rate at site 1 was affected by mutations in the tail of NBD2, the authors suggested that composite site 1 remained associated in closed channels. Our thermodynamic studies [3], examining state-dependent changes in energetic coupling between pairs of residues on opposing faces of site 1, supported this idea. A lack of change in energetic coupling for three such pairs was interpreted to be consistent with the interface around composite site 1 remaining "closed" throughout the gating cycle.

A more detailed analysis of the changes in gating kinetics caused by two site 1 perturbations has, however, lead us to question this initial interpretation. We focused on the effects of P-ATP dependent on site-1 occupancy and of the H1348A mutation in the NBD2 tail. Both site-1 perturbations had similar effects on gating: a 2-3 fold decrease in the non-hydrolytic closing rate (k-1, Fig. 1C) and in the rate of the O1→O2 transition (k1), consistent with the changes in site 1 causing a selective stabilization of state O1 with respect to both posthydrolytic O2 and closed C1. The pore-closing O2→C2 step was not affected. Could the lack of histidine/presence of phenylethyl moiety in site 1 be altering the energetics of other parts of the protein (e.g. TMDs and site 2) without site 1 actually moving during opening and hydrolysis? This interpretation would require that the site 1 perturbations (which cause an increase in the energetic barriers the channel must overcome to exit the O1 state) have different effects on the O1 ground state and on the transition states of the opening and hydrolysis steps. It is difficult to envisage how such differential allosteric effects could occur if the region around the perturbation remained static. A simpler interpretation of the data is that the physicochemical environment around the 1348 histidine side chain and around the N6 group on the adenine is not identical in O1 and in those transition states. In other words, this region of site 1 moves during opening and coincident with hydrolysis at the active site 2.

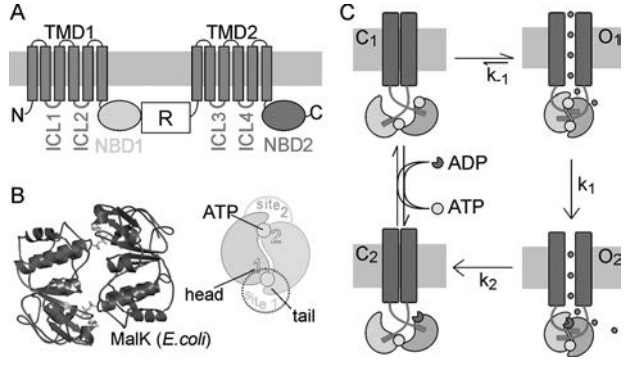

Fig. 1 A: Topology of CFTR. B: NBDs form head-to-tail dimers, with two ATP molecules at the interface. C: While ATP remains bound, unhydrolysed, at site 1 (lower composite site) ATP binding and hydrolysis at site 2 are coupled to CFTR pore opening and closing, respectively.

Employing chemical biology to define the molecular defects caused by the major Cystic Fibrosis mutant, F508del-CFTR

C. Bear, P.D. Eckford, M. Ramjeesingh and C. Li

The Hospital for Sick Children, Toronto, ON, Canada

Cystic Fibrosis is caused by loss of function mutations in the Cystic Fibrosis Transmembrane Conductance Regulator Gene: CFTR and is associated with severe airway disease. Loss of CFTR channel function on the surface of epithelial cells leads to mucus obstruction with recurrent infection. Drug discovery efforts have identified a "potentiator" drug (Ivacaftor or VX-770) that partially repairs the defective channel activity exhibited by the rare CF causing mutation: G551D and leads to improved lung function. Now, there is an urgent need to find a compound (or compounds) to rescue the defects caused by the major CF causing mutation: F508del present on at least one allele in 90% of CF patients. The F508del mutation causes the CFTR protein to misfold, leading to its retention in the endoplasmic reticulum and degradation. "Corrector" compounds have been identified that improve folding and trafficking of F508del-CFTR to the surface of cultured cells. However, the lead corrector: VX-809, failed to show efficacy in clinical trials of patients homozygous for this mutation. A recent press release reported promising, yet variable results for Phase 2a clinical trials of the combination: VX-809 plus VX-770. Most patients exhibited a relatively modest increase in FEV1 -highlighting the requirement for further drug development. The discovery of better modulators of mutant CFTR protein will be enabled by understanding the mechanism of action of these existing compounds. We hypothesize that these compounds bind directly to modulate CFTR folding and function and tested this hypothesis in novel in-vitro assays, using purified and reconstituted Wt and mutant CFTR.

Our in-vitro studies show that the potentiator VX-770 directly modified the channel activity of purified and reconstituted purified CFTR proteins. Channel activity of purified protein was evaluated using both a proteoliposomal flux assay and in planar lipid bilayer studies. Regardless of the CFTR genotype, ie. Wt, F508del or G551D-CFTR, we observed an increase in channel activity of PKA phosphorylated CFTR protein in the presence of its natural activating ligand, ATP. Interesting, we also found that VX-770 enhanced channel activity of phosphorylated CFTR in the nominal absence of ATP, suggesting that it acts via a canonical pathway to modify the channel gate. Currently, we are employing chemical analogues of VX-770 to gain insight into the structural properties of the VX-770 binding site and the mechanism underlying ATP independent channel activity.

Interestingly, we found that the two corrector compounds: VX-809 (in clinical trial) and C18 (an analog of VX-809) also bind directly to Wt-CFTR, F508del-CFTR and G551D-CFTR. The binding of C18 led to enhanced ATP-independent channel activity in all three of these genotypes, suggesting that it may share a similar binding site as the VX-770 or its binding leads to similar conformational changes. In the case of the purified mutant, F508del-CFTR, the binding of VX-809 or C18 also induces a more stable protein conformation, with a reduced propensity to aggregate. This latter observation, likely accounts for the partial "rescue" effect of these compounds on the misfolding of F508del-CFTR. As in our studies of VX-770, we are employing chemical analogues of C18 to probe the properties of its binding site on mutant CFTR. We anticipate that these binding studies will report the structural defects caused by the

F508del-CFTR mutation and enable discovery of more efficacious corrector compounds.
Together, these studies support the use of small chemical molecules in probing the structural basis for folding and function of CFTR.

SA32

Relating genotypes to phenotypes

S.W. Omholt

Norwegian University of Science and Technology, Trondheim, Norway

One uses DNA information in at least four explanatory settings: as a pure marker where we do not make a direct link to any particular phenotype; when we by statistical means establish an association between one or more chromosomal regions and phenotypic variation; when we can document that a particular DNA variation (natural or imposed) does indeed cause a phenotype; and finally in a causally cohesive setting where we can also explain how the genetic variation causes the observed phenotype in terms of biophysical mechanism at the cell, tissue and organ system levels. Even though there are several challenges associated with the first three types of explanation, they are all dwarfed by those facing us in connection with the fourth type. But these are the ones to be overcome if we are to bridge the gap between the genotype and the phenotype with real understanding, and thus realize the disciplinary goals of both genetics (Bateson, 1906 p.190) and physiology (Gove, 1981).
The relation between genotype and phenotype can be conceptualized as a genotype-phenotype map (GP map), assigning a phenotype to each possible genotype. The concept is highly instrumental for physiological research and concords well with the disciplinary goals of physiology as they are laid out in the standard definition of the discipline: "the study of the functions and activities of living matter (as of organs, tissues, or cells) as such and of the physical and chemical phenomena involved" (Webster's Third New International Dictionary). Fulfilling these goals demands an understanding of the mechanisms underlying the GP map.
The GP map concept applies to any time point in the ontogeny of a living system and it is an abstraction of a relation that is the outcome of very complex dynamics that include environmental effects. The concept does not imply that DNA has a privileged place in the chain of causality authorizing the current zoo of anthropomorphic concepts we attribute to it (Omholt, 2012; Noble, 2012). As advocated by Omholt (2012), DNA allows a system to induce perturbations of its own dynamics as a function of its own system state or phenome. Thus there is no direct causal arrow from genotype to phenotype in the sense that DNA is responsible for exerting a direct effect as a sub-system on the system dynamics. The causality flows from the system state through a change in use of DNA (as an inert system component) that results in a change in the production of RNA and protein, which in turn perturbs the system's dynamics. In those cases where variations in DNA cause changes in the perturbation regime it may lead to different system dynamics and thus physiological variation. This way of perceiving the function of DNA in a GP map context brings physiology back as the major arena for understanding the manifestation and propagation of genetic variation.
The talk will elaborate on the above concepts and show how computational physiology is the key to combine genetics and physiology. Starting out from simple illustrations on how to analyse genetic concepts within a systems dynamics framework, the talk will present current work to link genetics with mechanistic multiscale and multiphysics model descriptions of high-dimensional phenotypes by use of so-called causally cohesive genotype to phenotype models (cGP models). It will be shown how this approach is capable of providing a direct link between genetic variation, molecular regulatory biology and phenotypic variation. It can therefore be used to build theory about heredity phrased in terms of regulatory principles, something which standard genetic concepts and approaches are incapable of.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA33

Cross-species cloning: influence of cytoplasmic factors on development

Y. Sun

Institute of Hydrobiology, CAS, Wuhan, China

The crosstalk between naive nucleus and maternal factors deposited in egg cytoplasm before zygotic genome activation is crucial for early development of vertebrates. However, it is difficult to clarify the relative roles of zygotic and cytoplasmic factors in normal developing embryos, in which both types of factors were derived from the same species. Cross-species nuclear transfer provides an ideal system to study the relative role and crosstalk between egg cytoplasm and zygotic nucleus in development.
In most studies of nuclear transplantation, the cloned animals were obtained by intraspecies nuclear transfer and are phenotypically identical to their nuclear donors. In fishes, however, cross-species nuclear transplantation could be achieved in quite a few species. By transferring nuclei from transgenic common carp (Cyprinus carpio) into enucleated eggs of goldfish (Carassius auratus), we generated seven cross-genus cloned transgenic fish. Nuclear genomes of the cloned fish were exclusively derived from the nuclear donor species, common carp, whereas the mitochondrial DNA from the donor carp gradually disappeared during the development of nuclear transfer (NT) embryos. The somite development process and somite number of nuclear transplants were consistent with the recipient species, goldfish, rather than the nuclear donor species, common carp. This resulted in a long-lasting effect on the vertebral numbers of the cloned fish, which belonged to the range of goldfish. These demonstrate that fish egg cytoplasm not only can support the development driven by transplanted nuclei from a distantly related species at the genus scale but also can modulate development of the nuclear transplants.
Although cross-species NT could be used to retain the genetic viability of a species near extinction, most embryos produced by cross-species NT were unable to develop to later stages due to incompatible nucleo-cytoplasmic interactions between the donor nuclei and the recipient cytoplasm from different species. To study the early nucleo-cytoplasmic interaction in

cross-species NT, two laboratory fish species, zebrafish (Danio rerio) and Chinese rare minnow (Gobiocypris rarus), from different subfamilies were used to generate cross-subfamily NT embryos. Suppression subtractive hybridization (SSH) was performed to screen out differentially expressed genes from the forward and reverse subtractive cDNA libraries. After dot blot and real-time PCR analysis, 80 of 500 randomly selective sequences were proven to be differentially expressed in the cloned embryos. Among them, 45 sequences shared high homology with 28 zebrafish known genes, and 35 sequences were corresponding to 22 novel expressed sequence tags (ESTs). Based on functional clustering and literature mining analysis, the up- and down-regulated genes in the cross-subfamily cloned embryos were mostly found to be relevant to transcription and translation initiation, cell cycle regulation, protein binding, etc. Therefore, it is concluded that the fish egg cytoplasm could not only support the division and development of nuclei from another species, but also exert impact on the cellular homeostasis of the cross-species clones at different levels of biological processes.

Zebrafish and Chinese rare minnow were also utilized to produce mutual crossbred embryos, zebrafish ♀ X Chinese rare minnow ♂ (ZR) and Chinese rare minnow ♀ X zebrafish ♂ (RZ), and to examine the impact of cytoplasm from different species on a common type of nucleus. Although these two types of crossbred embryos originated from common nuclei of the same genetic materials, various developmental capacities were gained due to different origins of the egg cytoplasm. Using cDNA amplified fragment length polymorphism (cDNA-AFLP), we compared transcript profiles between the mutual crossbred embryos at two developmental stages (50%- and 90%-epiboly). Three thousand cDNA fragments were generated in four cDNA pools with 64 primer combinations. All differentially displayed transcript-derived fragments (TDFs) were screened by dot blot hybridization, and the selected sequences were further analyzed by semi-quantitative RT-PCR and quantitative real-time RT-PCR. Compared with ZR embryos, 12 genes were up-regulated and 12 were down-regulated in RZ embryos. The gene fragments were subjected to BLASTN analysis. The sequences encoded various proteins which functioned at various levels of proliferation, growth, and development. One gene (ZR6), dramatically down-regulated in RZ embryos, was chosen for loss-of-function study. The knockdown of ZR6 gave rise to the phenotype resembling that of RZ embryos.

All these evidences reveal that fish nucleus developing in the circumstance of egg cytoplasm could be largely influenced by the cytoplasmic factors. Therefore, developmental process should be interpreted in a systematic way rather than in a way that solely focuses on the role of nuclear genome.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA34

The Read-Write (RW) genome

J.A. Shapiro

Dept. of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, USA

The genome is traditionally treated as a Turing tape or Read-Only Memory (ROM) subject to change by copying errors. This default assumption of accidental mutation arose from the inevitable ignorance of the mechanisms of genome change in the 19th and early 20th Centuries. It contributed to the historical divorce between physiology, homeostasis and regulation, on the one hand, and studies of genetics and evolution, on the other.

In contrast to early assumptions about genomic accidents, research dating back to the 1930s has shown that genetic change is the result of cell-mediated processes, not simply damage to the DNA. McClintock's study of X-ray mutagenesis found that this mode of induced genome change arose because ionizing radiation caused chromosome breakage and cells have the capacity to detect, mobilize and join broken ends together, generating chromosome rearrangements (McClintock 1984; McClintock 1987). In other words, X-ray mutagenesis resulted from a physiological response to genome damage.

This cell-active view of genome change applies to all scales of variation, from point mutations to large-scale genome rearrangements and whole genome duplications (WGDs) (Shapiro 2011). As with X-rays, we now recognize all mutagen-induced change to result from the action of error-prone repair processes. The smallest "point mutations" involve the action of so-called "trans-lesion mutator polymerases" (Napolitano, Janel-Bintz et al. 2000; Goodman 2002).

Larger chromosome changes involve biochemical repair of double-strand breaks by "non-homologous end-joining" (NHEJ) complexes (Lieber, Gu et al. 2010) or the action of mobile genetic elements (Kazazian 2004; Nakayashiki 2011). Many large changes, including whole genome duplication (WGD), occur because of epigenetic modifications in response to stress conditions, chemical stimuli, or breeding between different species (http://shapiro.bsd.uchicago.edu/ExtraRefs.CellularRegulationNaturalGeneticEngineering.shtml, http://shapiro.bsd.uchicago.edu/ExtraRefs.WholeGenomeDoublingCriticalStagesEvolution.shtml, http://shapiro.bsd.uchicago.edu/TableII.7.shtml, http://shapiro.bsd.uchicago.edu/TableII.8.shtml, and http://shapiro.bsd.uchicago.edu/TableII.10.shtml). Moreover, cell-mediated changes to the genome can be targeted to particular locations in the genome by well-established molecular mechanisms (http://shapiro.bsd.uchicago.edu/TableII.11.shtml). It is possible, therefore, to begin understanding the genome evolutionary process as a sophisticated physiological response to ecological modifications and disruptions.

The take-home lesson of this lecture is that DNA changes are biological (biochemical, physiological) and not accidental in origin. Consequently, it is necessary to revise our concept of genome storage to accommodate the potentials of a Read-Write (RW) storage system. The evolutionary implications of this conceptual change are profound. Cell inscriptions on the genome, like all biochemical and physiological activities, are subject to regulation by control circuitry, in particular epigenetic controls. The interactions between these control circuits and the environment make it possible to begin a detailed experimental investigation of the relation between ecological and genomic changes in evolution.

Computational biology as a tool for reverse engineering genotype-phenotype relations

C. Cha[1,2], Y. Himeno[2], T. Shimayoshi[3], Y. Nakamura[4], E. Santos[2], A. Amano[2] and A. Noma[2]

[1]OCDEM, University of Oxford, Oxford, UK, [2]Bioinformatics, Ritsumeikan University, Ritsumeikan, Japan, [3]ASTEM Research Institute of Kyoto, Kyoto, Japan and [4]Diabetes and Clinical Nutrition, Kyoto University, Kyoto, Japan

Electrically excitable cells generate time-dependent change in transmembrane potential (action potential), which arises from complex interactions among ion channels and transporters expressed in the membrane. To understand how the excitable cell regulates its function, it is important to elucidate the role of individual channels in generating particular shape of action potentials. Conventionally, inhibition or knock-out methods have been used in experimental or even in mathematical modelling studies. However, inhibition of one kind of channel always induces unintended modification of the rest of channels through the complex interaction, and then the response cannot be considered as the effect of the channel of interest. We developed a new analytical method- lead potential analysis, which can be applied to any electrophysiological cell models and calculate contribution of each cellular component to membrane potential change in a quantitative way, not interfering with normal cellular condition. In this presentation, I demonstrate the recent studies to apply lead potential analysis, in which the electrical mechanisms were successfully elucidated in cardiac sinoatrial node cell and pancreatic beta cell.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The modern synthesis: extension or replacement?

G.B. Müller

Department of Theoretical Biology, University of Vienna, Vienna, Austria

Since the time of the last major theoretical integration in evolutionary biology, the Modern Synthesis of the 1930s and 1940s, the biosciences have made significant advances, and today's evolutionary biology operates with numerous concepts that were not part of the original synthesis. Since the retrospective subsumption of these novel concepts under the well defined Synthesis framework is impossible, propositions for a new and extended evolutionary synthesis are on the rise. One characteristic feature of such revised models is the shift from the population dynamic emphasis, favored by the traditional approach, towards a causal-mechanistic explanation of phenotypic complexity. The integration, for instance, of organizing relations between genes, cells, and tissues in development, as well as the interactions of these processes with physiological and environmental factors, entails a revised understanding of the evolutionary role of natural selection. It will be argued that not only the kind and number of theory elements have increased, but their inclusion also modifies the formal structure of evolutionary theory and expands its explanatory capacity.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Generating and regenerating blood and the cardiovascular system

R. Patient

University of Oxford, Headington, UK

Blood cells are turned over rapidly and we carry a relatively modest number of stem cells to regenerate them. One of the key properties to understand is how these cells stably maintain the undifferentiated state. To study this, we have taken the approach of determining how these cells are programmed. We have lineage traced the cells in Xenopus and zebrafish embryos to determine their history and the niches that they occupy. We have then searched these niches for the signals that programme the cells. We have also begun to identify the nuclear responses to these signals that lead to the establishment of a stable networks of transcription factors that specify cell fate. We have taken a similar approach to the myocardium, and more recently have begun to compare normal development with regeneration. We are attempting to identify the cells, signals and transcriptional networks involved in this process, an understanding of which could inform regenerative strategies in the human heart.

The fate of mesothelial cells and their role in tissue homeostasis

T. Benameur[1,2], W. Qing[2], A. Thornburn[2], P. Hohenstein[2], N. Hastie[2] and B. Wilm[1]

[1]Cellular and Molecular Physiology, University of Liverpool, Liverpool, UK and [2]MRC Human Genetics Unit MRC IGMM, MRC IGMM University of Edinburgh, EDINBURGH, UK

Mesothelium consists of a monolayer of specialized cells known as mesothelial cells that form during embryonic development over internal organs and line peritoneal, pleural and pericardial cavities. Mesothelial cells have been shown to undergo

epithelial-mesenchymal transition (EMT) and during embryonic development differentiate into a variety of cells including vascular smooth muscle cells in the heart, lungs and intestine, fibroblast cells and cardiomyocytes. Recent studies have shown that the mesothelium of the heart, the epicardium, contributes to the coronary vasculature during embryonic development and is involved in repair mechanisms in injury models of the heart and liver.
In order to determine which tissues and organs mesothelial cells contribute to during embryonic development and how they maintain adult tissue homeostasis, we have established a lineage tracing strategy using a mesothelial-specific Cre (Recombinase) mouse line.
In order to demonstrate a stem/progenitor cell role of mesothelial cells, Tamoxifen was administrated to pregnant or adult mice carrying the mesothelial-specific CreERT2 construct, in combination with a Rosa26-based reporter, for short and long term pulse-chase experiments. Our results indicate that mesothelial-derived cells contribute to a range of tissues in the developing embryo and in the adult. Specifically, in embryos, mesothelial cells contributed to the formation of vascular structures in developing kidneys. Furthermore, in adult mice, our analysis revealed that Tamoxifen pulse induced recombination is dose and route of administration dependent, leading to significant recombination of reporter alleles which can be detected weeks after Tamoxifen injection. As a consequence of mesothelial-specific lineage tracing, we found clonal distribution of labelled cells in the mesothelium of all internal organs, including the heart, lungs, intestine, spleen, and kidney.
Here, we will present our current understanding of the dynamics of mesothelial cell contribution to tissue maintenance and regeneration. Further, we will discuss that duration and route of Tamoxifen administration are important parameters that need to be considered during Tamoxifen-induced lineage tracing studies.

HIFs, metabolism, and tumor progression

M.C. Simon

Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, USA

Solid tumors exhibit heterogeneous microenvironments, often characterized by limiting concentrations of oxygen (O2), glucose, and other nutrients. How oncogenic mutations alter stress response pathways, metabolism, and cell survival in the face of these challenges is incompletely understood. Here, we report that constitutive mTORC1 activity renders hypoxic cells dependent on exogenous desaturated lipids, as levels of de novo synthesized unsaturated fatty acids are reduced under low O2. Specifically, we demonstrate that hypoxic Tsc2-/- cells deprived of serum lipids exhibit a magnified UPR response, but fail to appropriately expand their ER, leading to IRE1-dependent cell death that can be reversed by the addition of unsaturated lipids. UPR activation and apoptosis were also detected in Tsc2-deficient kidney tumors. Importantly, we observe this phenotype in multiple human cancer lines and suggest that cells committed to unregulated growth within ischemic tumor microenvironments are unable to balance lipid and protein synthesis due to a critical limitation in desaturated lipids.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Notch signals and intestinal stem cells: from crypt homeostasis to colon cancer

S. Fre

Developmental Biology and Genetics, Institut Curie, PARIS, France

In adult organisms, tissues are maintained and repaired by stem cells, which divide and differentiate to generate more specialized progeny. The mechanisms that control the balance between self-renewal and differentiation promise fundamental insights into the origin and design of multi-cellular organisms. A tissue that is particularly suited to approach these questions is the intestinal epithelium, as it consists of a monolayer of epithelial cells that endlessly divide, migrate while differentiating and are replaced to ensure continuous and fast cell renewal throughout adult life. In this tissue, somatic stem cells represent crucial elements that govern tissue remodeling and homeostasis and the combined work of several laboratories has provided evidence for the existence of at least two different stem cell populations in the small intestinal crypt. In this program, we focus on the Notch signaling pathway as a new promising marker to study gut stem cell physiology. Our observations indicate that the Notch1 receptor is expressed in both crypt stem cell populations, implying that it can mark either one of the two in vivo and providing a precious tool to dissect the hierarchy between these different stem cells.
Notch signaling plays an evolutionarily conserved role in metazoans, which basically consists in mediating cell coordination in development and during adult tissue homeostasis, through the profound effects it has on stem cells. The precise identity of the cells in which Notch signaling is active is still unclear, mainly due to the lack of reliable tools to investigate Notch expression in vivo. For this purpose, we have recently developed and characterized a novel roster of unique transgenic mice that permit to assess Notch expression and activation in vivo in an unprecedented fashion. Thanks to these novel mice, we have been able to formally show that the expression of the Notch1 receptor and of its transcriptional target Hes1 identifies crypt stem cells. We are now using these mouse models to dissect the hierarchy between stem cell populations in the small intestine, while expanding our knowledge on colonic stem cells, that remain poorly studied. In addition, we study the dynamic behavior of stem cells during regeneration upon injury.
The critical role played by Notch signaling in intestinal renewal and differentiation, as well as in tumorigenesis in this tissue, is exemplified by the vast number of reports on this topic appeared in recent years (i.e. [1-6]). In the past five years, the Notch signaling pathway has emerged as an essential regulator of intestinal homeostasis; indeed Notch signals can control the segregation of each mature lineage from undifferentiated progenitor cells, and they are instrumental for maintaining the proliferating intestinal cell pool. When Notch signaling is inhibited, all crypt cells cease to proliferate and differentiate into secretory cells [4]. Reciprocally, we have shown that gain of Notch function in the developing intestinal epithe-

lium dramatically impairs cell differentiation and increases the proportion of dividing cells [2]. The role of Notch in promoting intestinal proliferation requires Wnt signals, whereas it specifies cell fate independently of Wnt [5]. Importantly, our work has shown that Notch acts in synergy with the Wnt pathway to induce intestinal polyps [5]. The accumulated evidence in both systems supports a role for Notch in expanding a potentially malignant cell population and hence increasing the chances of a tumorigenic event. It is indeed widely accepted that the primary events in tumourigenesis are linked to stem cell transformation: the process of tumor development is thought to initially affect normal stem cells or closely related early progenitors. In order to establish the identity of Notch1-expressing cells within a tumor and to follow their fate in vivo, we have crossed N1-CreERT2/GFP mice to Apc heterozygous animals, which give rise to intestinal tumors by stochastic loss of heterozygosity (LOH) at the Apc locus. Our novel genetic fate-mapping system will consent to identify which cells within a tumor express the Notch1 receptor, as well as to follow the progeny of the Notch-expressing tumor cells. Our preliminary results show that only a small fraction of tumor cells expresses the N1cre-driven GFP reporter. These experiments will allow us to highlight in vivo which and how many cells within a tumor present Notch activity.

Our research aims at understanding the molecular features of adult stem cells, as well as the mechanisms by which Notch signaling controls the fate of specific cell populations during regeneration and tumourigenesis. We believe that the identification of common organizational principles of tissue architecture is an essential step in order to develop safe and efficacious applications of stem cells in regenerative medicine.

CD133+ progenitors and regeneration of the renal tissue: from cells to vesicles

B. Bussolati

Dept of Molecular Biotechnology and Health Sciences, University of Torino, Torino, Italy

The tubular compartment of the nephron displays a high regenerative ability. We previously isolated CD133+ stem/progenitor cells in the tubular compartment of the human kidney(1-3). However, their possible contribution to repair is unknown. We here evaluated the possible modulation of CD133+ cells by the hypoxic environment, the molecular mechanisms involved and their possible involvement in renal regeneration.

CD133+ progenitors cultured under hypoxia (1%O2) showed increased proliferation and clonogenic ability. When injected in vivo, CD133+ hypoxic progenitors showed ability to differentiate in structures resembling the different segments of the nephron. Moreover, hypoxia up-regulated Oct-4 isoforms in CD133+ cells via regulation of the Oct4 promoter. In parallel, hypoxia downregulated microRNA-145, known to act as an Oct4 transcriptional repressor. Epithelial differentiation increased microRNA-145 and reduced Oct4 level, suggesting a balance between Oct4 and microRNA-145. Labelled CD133+ progenitors localized into the injured kidneys in a model of acute renal damage and promoted renal functional regeneration. In addition, modulation of the HIF pathway through PHD2 inhibitors increase EPO production by CD133+ cells. These results suggest that hypoxia may direct CD133+ progenitors toward a more stem phenotype via Oct4A/miR145 balance. The plasticity of renal CD133+ cells could be exploited in renal regeneration after hypoxic damage. Among the mechanisms that may be involved in the regenerative properties of CD133+ cells, release of growth factors and of microvescicles were investigated. Results show that hypoxic CD133+ cells release microvescicles enriched in microRNA and that exosome injection may directly mediate their in vivo effect in a model of acute kidney injury.

Pathophysiology of human heart failure: importance of skeletal muscle myopathy and reflexes

M.F. Piepoli[1] and A. Crisafulli[2]

[1]Heart Failure Unit, Cardiac Dept, G. da Saliceto Hospital, AUSL Piacenza, Italy and [2]Department of Medical Sciences, Sports Physiology Lab, University of Cagliari, Cagliari, Italy

The origin of symptom of exercise intolerance is still considered one of the major challenges among scientists and clinicians involved in the care of patients with chronic heart failure (CHF). In contrast to the traditional vision that saw a malfunction of the heart as a pump as the leading cause, in the last 20 years there has been mounting evidence that the complex pathophysiology of CHF begins with an abnormality

of the heart as a "*primum movens*", but involves adaptive changes in many body parts, including the cardiovascular, musculoskeletal, renal, neuroendocrine, haemostatic, immune, and inflammatory systems. These systems' changes are playing key roles in the HF expression and progression. Alterations in skeletal muscle mass are also of importance in limiting peak functional capacity in patients with CHF, as reduced physical activity (disuse and immobilisation in advanced stages) plays some part in the muscle alterations in CHF. On the whole, these abnormalities resemble those induced by physical deconditioning. A great bulk of evidence, originally from our Lab., has pointed towards the existence of a reflex network that becomes hyperactive secondary to skeletal muscle alterations due to peripheral modification including early occurrence of acidosis, early depletion of high energetic metabolic factors, particularly in the skeletal muscle. The overactivation of signals originating from skeletal muscle receptors (mechano-metaboreceptors) is an intriguing hypothesis proposed to explain the origin of symptoms and the beneficial effect of exercise training in the CHF syndrome. These reflexes may contribute to sympathetic overactivation, to exercise intolerance, and to the progression of CHF syndrome. The so called metaboreflex has been demonstrated to be hyperactive in CHF and to be responsible for paradoxical increase in systemic vascular resistance and decrease in cardiac output whenever activated in these patients. Recently, it was found in heart transplant recipients that, after transplant, despite improved cardiac function, re-setting of metaboreflex-induced cardiovascular adjustments to exercise requires months in these patients, thereby suggesting that this reflex was dys-regulated before transplant.

Skeletal muscle dysfunction in heart failure and its reversal by exercise training

P.C. Brum

School of Physical Education and Sport, University of Sao Paulo, São Paulo, São Paulo, Brazil and Circulation and Medical Imaging, Norwegian University of Science and Technology, Trondheim, Norway

Skeletal myopathy plays a prominent role in heart failure (HF) symptoms since skeletal muscle myopathy worsens with HF progression and parallels exercise intolerance observed in HF individuals. HF-induced skeletal muscle myopathy includes morphological and functional changes along with derangements in skeletal muscle metabolism and autonomic function. We have demonstrated that autonomic dysfunction, such as sympathetic hyperactivity, contributes to the skeletal myopathy in HF. Mice with sympathetic hyperactivity-induced HF (Brum et al 2002) display skeletal myopathy characterized by exercise intolerance, skeletal muscle pro-oxidant state (marked by decreased redox balance and increased lipid hydroperoxidation) and skeletal muscle wasting (Bacurau et al 2009, Bueno et al 2010). The latter is associated with increased proteolysis by the ubiquitin-proteasome system (Cunha et al 2012).
Aerobic exercise training is a powerful tool counteracting skeletal muscle myopathy. We have observed reduced muscle noradrenaline levels and oxidative stress associated with improved exercise capacity and re-established muscle mass in HF (Bacurau et al 2009). The mechanism by which aerobic exercise training prevents/attenuates skeletal muscle atrophy is unclear. Recent data from our group suggest that aerobic exercise training improves protein synthesis by increasing skeletal muscle IGF-1/PI3K/Akt signaling pathway in HF mice (Bacurau et al, unpublished results). Interestingly, we have also demonstrated that aerobic exercise training reduces protein catabolism. Aerobic exercise training decreased mRNA levels of the main skeletal muscle atrophic genes (MuRF and Atrogin-1/MAFbx) and reestablished proteasome activity in both mice and humans with HF (Cunha et al 2012).
Collectively, our studies suggest that aerobic exercise training promotes remarkable adaptations in skeletal muscle in HF that counteract skeletal myopathy. Regarding skeletal muscle wasting, aerobic exercise training prevents atrophy leading to a better balance between protein synthesis and degradation. Therefore, aerobic exercise training is a powerful non-pharmacological therapy for HF.

Modifiers of heart and muscle function: where genetics meets physiology

E.M. McNally

University of Chicago, Chicago, IL, UK

Many single gene disorders are associated with a range of symptoms that cannot be explained by the primary genetic mutation. In humans, this is clearly seen in individuals with the identical loss of function mutation in Sgcg, the gene encoding the dystrophin associated protein gamma-sarcoglycan. Like their human counterparts, Sgcg mice develop progressive muscle wasting and weakness along with dilated cardiomyopathy. To identify genetic regions that modify outcome in muscular dystrophy and cardiomyopathy, we used an intercross strategy. Sgcg mice in the DBA2/J or 129T2/SvEmsJ were intercrossed, representing severe and mild forms of disease, respectively. Nearly 200 mice were analyzed using echocardiography in vivo, and ex vivo analysis of muscle and heart for mass, hydroxyproline content and Evans blue dye uptake as indicators of muscle fibrosis and damage. Genomewide profiling was conducted and identified 40 suggestive QTLs and 12 significant QTLs. A second intercross using the Sgcg allele in the DBA2/J background was generated with the superhealing MRL background. Genomewide analysis identified a locus on chromosome 2 that regulates cardiopulmonary function. These data indicate that mouse models of muscular dystrophy

and cardiomyopathy can be used to identify modifier loci that correlate with outcome. The identification of the genes responsible for these QTLs will help define the pathological defects of cardiopulmonary dysfunction.

Autonomic, locomotor and cardiac abnormalities in a mouse model of muscular dystrophy: targeting the renin angiotensin system

R. Sabharwal

Internal Medicine, University of Iowa, Iowa City, IA, USA

Muscular dystrophies are a heterogeneous group of genetic muscle diseases characterized by muscle weakness and atrophy. Mutations in sarcoglycans and other subunits of the dystrophin-glycoprotein complex cause muscular dystrophy and dilated cardiomyopathy (DCM) in animals and humans [1]. Aberrant autonomic signaling is recognized in several neuromuscular disorders. Antagonists of the renin angiotensin system (RAS) have been shown to attenuate skeletal muscle pathology in mouse models of muscular dystrophy [2]. Furthermore, treatment with an angiotensin converting enzyme inhibitor and β-adrenergic receptor blocker has been shown to reduce symptoms of congestive heart failure in Duchenne muscular dystrophy [3].

Thus, we hypothesized that activation of the RAS contributes to skeletal muscle and autonomic dysfunction in mice deficient in sarcoglycan-δ (Sgcd) at a young age; and this early autonomic dysfunction contributes to later development of left ventricular (LV) dysfunction and increased mortality. We measured cardiac function (echocardiography); blood pressure (BP), heart rate (HR) and locomotor activity (radiotelemetry); spontaneous baroreflex sensitivity (BRS, sequence technique); cardiac sympatho-vagal tone (HR responses to propranolol and atropine, respectively); and survival (Kaplan-Meier) in conscious Sgcd-/- and control mice.

We demonstrated that young, 10 wk old Sgcd-/- mice exhibit histopathological features of skeletal muscle dystrophy (fibrosis, centralized nuclei), oxidative stress, decreased locomotor activity and severe autonomic dysregulation, but normal cardiac function [4]. Autonomic function continued to deteriorate in Sgcd-/- mice with age and was accompanied by LV dysfunction and DCM at older ages (>50 wks) [5]. Autonomic dysregulation at a young age predicted later development of LV dysfunction and high mortality in Sgcd-/- mice [5].

Angiotensin II (AngII) acting via type 1 receptors (AT1R) causes oxidative stress, fibrosis, and cardiovascular and autonomic dysfunction, while Ang[1-7] acting via Mas receptors counteracts these deleterious actions [6]. Subgroups of control and Sgcd-/- mice were treated with either the AT1R blocker losartan (10 mg/ml, drinking water) or Ang[1-7] (2.5mg/kg/day, osmotic pump) for 8 wks beginning at 3 wks of age. Both losartan and Ang[1-7] decreased AT1R expression, oxidative stress, and fibrosis in skeletal muscle, increased locomotor activity, and prevented autonomic dysfunction in Sgcd-/- mice without affecting these measures in control mice.

Summary: We conclude that activation of RAS, at a young age, contributes to skeletal muscle and autonomic dysfunction in muscular dystrophy. We speculate that the latter is mediated via abnormal sensory nerve and/or cytokine signaling from dystrophic skeletal muscle to brain, and contributes to age-related LV dysfunction, DCM, arrhythmias and premature death. Therefore, correcting the early autonomic dysregulation may provide a novel therapeutic approach in muscular dystrophy.

Maintaining skeletal muscle mass: lessons learned from hibernation

R.D. Cohn

Paediatrics, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada

Maintaining skeletal muscle mass is essential for general health and prevention of disease progression in various neuromuscular conditions. Here we provide an innovative approach to evaluate the mechanisms underlying muscle preservation in a naturally occurring hibernating animal that is protected from muscle atrophy despite prolonged periods of immobilization and starvation. We find that absence of proteolysis and autophagy accompanied by increased protein synthesis during hibernation is regulated independent of Akt. These observations challenge the current paradigm that Akt is the major determinant and regulator of skeletal muscle mass and homeostasis. Instead, we demonstrate that serum- and glucocorticoid-inducible kinase, SGK, represents a novel mediator of skeletal muscle homeostasis and function in hibernating and non-hibernating mammals. Our results thus identify a novel therapeutic target to combat loss of skeletal muscle mass in a variety of conditions associated with muscle atrophy and degeneration. Furthermore, we will demonstrate how these pathways are regulated in cardiac muscle during hibernation and thus emphasize the versatility of biological protection of numerous tissues during prolonged periods of decreased blood flow and metabolism.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Extracellular matrix remodeling in the post-myocardial infarction aging heart

A. Yabluchanskiy[1,3], Y. Ma[1], Y. Jin[2] and M. Lindsey[1,3]

[1]Physiology & Biophysics, Univ MS Medical Center, Jackson, MS, USA, [2]Electrical and Computer Engineering, UTSA, San Antonio, TX, USA and [3]Research Service, G.V. (Sonny) Montgomery Veterans Affairs Medical Center, Jackson, MS, USA

Aging impairs the ability of the left ventricle (LV) to respond to stress or injury. Cardiac aging is characterized by increased inflammation, an accumulation of extracellular matrix (ECM), and the development of diastolic dysfunction. Matrix metalloproteinases (MMPs) are key enzymes that regulate ECM turnover, and in particular MMP-9 deletion has been shown to attenuate LV dysfunction and remodeling post-myocardial infarction (MI) in young mice, by coordinating inflammatory and ECM responses. MMP-9 levels rise with age, in both the LV and plasma. The increase in cardiac MMP-9 is due to an accumulation of macrophages, which contribute to the increase in inflammation and ECM. Aging, therefore, gradually resets the cardiac environment. This talk will discuss the outcomes when myocardial infarction (MI) is superimposed on a cardiac aging background, focusing on changes to the inflammatory response that coordinate infarct scar formation and how MMP-9 deletion regulates these changes in the aging setting.

Lysyl oxidase, collagen cross-linking, and cardiac dysfunction

J.D. Gardner, J.M. Bradley and M.C. El Hajj

Physiology, LSU Health Sciences Center, New Orleans, LA, USA

Heart failure develops when compensatory mechanisms fail to overcome injury and hemodynamic stress that can be caused by myocardial infarction, pressure and volume overload, or hypertension. Increased stress on the heart results in a reorganization of the myocardial extracellular collagen matrix (ECM), leading to fibrosis and dysfunction. Lysyl oxidase (LOX) is critical for the enzymatic cross-linking necessary for normal collagen processing, yet over-activation of LOX is associated with fibrosis. LOX is significantly elevated in failing human hearts, but it is not known if excess LOX activity accelerates cardiac failure. Using a rodent model of heart failure, we assessed the role of LOX activity in the progression of cardiac dysfunction and adverse ECM alterations. Statistical analyses were performed using one-way ANOVA with Dunnett's post test, and considered significant at $p<0.05$. Surgically induced volume overloaded and sham-operated rats were studied at 14 wks post-surgery (n=5 to 7 per group). To assess the role of LOX in disease progression, rats were treated with a LOX inhibitor (BAPN; 100 mg/kg/d) starting 2 wks post-surgery. LOX inhibitor or vehicle saline was delivered using Alzet osmotic minipumps implanted in the abdominal cavity. Echocardiography was used to evaluate cardiac function and progression of left ventricular (LV) remodeling. LV LOX expression and activity were determined by Western blot and Amplex red assay, respectively. Extracellular collagen assays included: interstitial fibrosis by picrosirius red staining of LV sections; cross-linking by pyridinoline content; and collagen type I and III expression by western blot. Volume overload (VO) caused significant ventricular dilatation (43% increase) and dysfunction (26% decrease, %FS) by 14 wks post-surgery versus Sham. LOX protein expression was increased (65%; $p<0.05$ vs Sham) by VO with concomitant increases in LOX activity. These increases in LOX were associated with significantly elevated interstitial collagen, cross-linking, and type I/III ratio ($p<0.05$ vs Sham). LOX inhibition prevented the development of cardiac dysfunction and blocked the VO-induced changes in LV collagen. LOX inhibition normalized LV collagen staining, cross-linking, and expression to levels comparable to age-matched Sham. Our findings indicate that LOX inhibition was cardioprotective in the volume overload stressed heart. Further studies are warranted to determine the cellular mechanisms responsible for increased LOX expression and LOX-dependent damage in the stressed heart.

G-protein coupled receptor signaling in the diseased heart

U. Mende

Medicine/Cardiology, Rhode Island Hospital & Brown University, Providence, RI, USA

Signal transduction via G protein-coupled receptors (GPCRs) is essential for the regulation of cardiovascular function, including heart rate, growth, contraction, and vascular tone. Pertubations in GPCR signaling have pathophysiological consequences and are major contributors to cardiac disease. Regulators of G protein Signaling (RGS proteins) belong to a diverse protein family that was originally discovered for their ability to accelerate signal termination in response to GPCR stimulation, thereby reducing the amplitude and duration of GPCR effects. Interaction of their common RGS domain with some $G\alpha$ subunits of heterotrimeric G proteins mediates their biologic regulation of GPCR signaling by limiting the interactions between $G\alpha$-GTP and $G\beta\gamma$ with intracellular or membrane effectors or ion channels. Additional functional domains in some RGS protein isoforms can facilitate protein-protein and protein-lipid interactions that confer additional regulatory functions. Several RGS proteins are expressed in the heart and have been implicated in the cardiac remodeling response and heart rate regulation. Changes in RGS protein expression and/or function are believed to participate in the pathophysiology of cardiovascular diseases including hypertrophy, failure, arrhythmias and hypertension.

Our investigations have focused primarily on RGS2, a member of the RGS R4 subfamily. RGS2 distinguishes itself from other

closely related RGS isoforms by its susceptibility to regulation and signaling specificity. Expression studies in isolated adult rat ventricular cardiomyocytes (CM) and cardiac fibroblasts (CF) revealed that - among the cardiac RGS isoforms - RGS2 is most susceptible to regulation and that this is a highly dynamic process. Short-term activation of the Gq/11 signaling pathway transiently up-regulates RGS2 mRNA in both CM and CF, which likely represents a negative feedback mechanism. Acute β-adrenergic or forskolin stimulation also markedly increases RGS2 mRNA, which points to potential crossregulation and desensitization between Gs- and Gq/11-mediated signaling pathways. Importantly, in contrast to acute stimulation, marked RGS2 down-regulation was discovered in vivo in ventricles subjected to pressure overload, CM from mice expressing constitutively active Gαq as well as CM and CF from rats subjected to prolonged Angiotensin II infusion, which has been implicated in exacerbating cardiac remodeling in stressed or injured hearts. Functionally, using a gain-of-function approach (adenoviral infection), we show that RGS2 is a potent negative regulator of Gq/11 signaling in both CM and CF but has no effect on sympathetic or parasympathetic regulation of adenylate cyclase (AC) or AC itself (as reported for other cell types). Using a loss-of-function approach (RNA interference), we demonstrate that endogenous RGS2 is a functionally important negative regulator of Gq/11-mediated CM hypertrophy and function as well as CF proliferation and collagen production.

It was previously shown that mice with generalized targeted deletion of RGS2 display enhanced hypertrophy and fibrosis in response to pressure overload (Takimoto et al., 2009), which is mediated in large part via Gq/11 signaling (Wettschureck et al., 2001). We generated a mouse model with α-myosin heavy chain promoter-driven RGS2 expression to investigate whether RGS2 overexpression in CM can be used to attenuate Gq/11 signaling and hypertrophy in vivo. Transgenic RGS2 was highly functional in negatively regulating Gq/11 signaling in atrial appendages and to a much lesser extent in ventricles. In ventricles (but not atrial appendages), RGS2-mediated modulation of Gq/11 signaling was absent after pressure overload induction by transverse aortic constriction (TAC), which may account for the lack of anti-hypertrophic effect we observed in transgenic mice. Importantly, TAC-induced RGS2 expression changes (down-regulation) did not underlie the functional differences we observed between atria and ventricles. Random insertion effect and changes in the expression of other RGS proteins were excluded as well.

Interestingly, our findings suggest that RGS2 function is differentially regulated in atria and ventricles in vivo, which could include differences in posttranslational modifications (such as phosphorylation and palmitoylation) that can modulate the effectiveness of RGS2 in exerting regulatory effects on GPCR signaling. Since transgenic overexpression of RGS2 was associated with highly effective inhibition of Gq/11 signaling in the atria, the new model can be utilized to advance understanding of atrial signaling and to mitigate Gq/11 signaling in the atrium for potential therapeutic purposes. The in vivo role of RGS2 in regulating CF signaling and function in both atria and ventricles under both physiological and pathophysiological conditions also remains to be explored.

SA50

Genetic modulation of heart failure progression

F. Sheikh

University of California-San Diego, La Jolla, CA, USA

Cardiovascular disease is the leading cause of death in developed countries. It is now clear that many cardiomyopathies leading to the progression of heart failure result from genetic mutations or alterations in the cytoskeletal network/basic structural components of the cardiac muscle. For the last five decades, the simplistic obligatory step of calcium binding to actin bound regulatory proteins (eg., troponin-tropomyosin complex) has contributed to the prevailing view that the control of calcium cycling and actin-bound regulatory proteins (thin filament proteins) dominates regulation of muscle contraction as well as underlie the dysregulation of contractile dynamics in heart failure. Several studies have shown that dysregulation of myosin regulatory proteins (thick filament proteins), such as myosin light chain-2 (MLC2), via dephosphorylation is associated with human cardiomyopathies and heart failure; however, mechanistic insights into its underlying role in cardiac muscle and heart disease remain poorly understood. Using integrative gene-targeted mouse and multi-scale computational models, we identify the mechanisms underlying an indispensable role for ventricular MLC2 (MLC2v) phosphorylation in regulating cardiac myosin cycling kinetics, which directly control actin-myosin interactions, while also surprisingly, feeding back to cooperatively influence calcium-dependent activation of the thin filament. Loss of these mechanisms uncovers previously unrecognized early cardiac muscle defects in the rates of twitch relaxation and ventricular torsion, which strikingly precede the left ventricular dysfunction of heart disease and failure in a novel non-phosphorylatable MLC2v mouse model. We show that in contrast to conventional views, there is a direct and early role for MLC2 phosphorylation in regulating actin-myosin interactions in striated muscle contraction and that dephosphorylation of MLC2 and loss of these mechanisms play a critical role in heart failure progression.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA51

Early epigenetic modulation of the diseased heart

L.M. Delbridge

Department of Physiology, University of Melboune, Melbourne, VIC, Australia

There is now an abundance of evidence to support the proposition that perinatal growth influences have long term impact on defining adult health status - cardiovascular health in particular. These investigations have highlighted the role that tissue modeling processes enacted in the early postnatal period play in setting the scene to ensure long term appropriate growth responses. Although the phenomenology of early disease 'origins' is generally accepted, understanding of the mechanisms involved is limited. The emphasis has been primarily on aspects of the gestational environment which influence fetal growth – ie nutritional state and other factors associated with uteroplacental insufficiency. Less is understood about how offspring genetic/epigenetic factors can operate inde-

pendently during the perinatal period to define subsequent tissue and organ growth.
The switch from proliferative (ie mitotic) to hypertrophic cellular growth occurs in the perinatal period as myocytes exit from the cell cycle, and beyond this period the myocardium is considered to be largely a terminally differentiated tissue. Thus, the myocyte population is essentially fixed at this time point, defining the non-replaceable pool of cells available to support ongoing maturational growth of the heart. As a highly metabolically active tissue, the heart is particularly vulnerable to substrate 'starvation' stress in the perinatal period, during transition from placental to lactational nutrition. To support energy homeostasis, autophagic activity is upregulated in multiple tissues during the neonatal starvation period – and particularly in the heart. A high level of autophagic activity can be lethal, and cell death by autophagy is recognized as a distinctive, non-apoptotic type of programmed cell death. Thus, myocyte loss through autophagy during the perinatal period has the potential to significantly deplete the heart cell population.
Recently, using novel experimental animal models, it has been possible to demonstrate a link between reduced cardiac myocyte population in the neonatal heart due to upregulated autophagy and abnormal cardiac enlargement in the adult. An interaction between angiotensin II/G-protein-coupled-receptor and IGF1/PI3Kinase-dependent signaling pathways is implicated in this neonatal growth suppression and autophagy induction. Furthermore there is emerging evidence that autophagy pre-disposition and the cross-talk between these signalling pathways is different in male and female hearts, and new findings that microRNA molecules (miR) are the key to sex-specific programming patterns of gene expression which have long-term tissue modeling influence on cardiac pathophysiology. Understanding the early epigenetics of disease predisposition has become an exciting and high priority research pursuit which will yeild important information about the mechanisms of sex difference in adult cardiac disease outcomes.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA52

Interactive pedagogies in physiology education

J. Kibble

Medical Education, University of Central Florida, Orlando, FL, USA

Population theorists have described different generations according to their demographics and the key life events they grew up with. Accordingly, these collective life experiences result in particular attitudes and behaviors that may characterize a generation. The Millennial generation was born from 1981 to 1999. Key events in their formative years include 9-11 and a decade of international wars. Millennial students have been shaped by immersion in technology, and by the nurturing of overprotective ("helicopter") parents. This generation of students is said to be optimistic, generous, open-minded and team-oriented. They value association to others, have high expectations of technology and are accustomed to structured environments, and to receiving regular feedback. Their challenges may include a lack of experience with unplanned environments and a tendency to worry (1,2).
At the University of Central Florida we have built a new medical school that has graduated its first class and received full accreditation in 2013. This has been a rare opportunity to design a new curriculum and build new facilities. Our curriculum has three phases: 1) Foundations, 2) Systems-based study of disease, 3) Translation to practice. The first two phases are comprised of integrated instructional modules that precede clinical clerkships. Our pedagogic approach seeks to maximize opportunities for active and independent learning and to be congruent with the traits of the current generation of learners.
To support the required knowledge base, all our students receive an iPad that is loaded with interactive textbooks and have access to a fully electronic medical library. They are given training in the use of medical databases and reference organization early in the curriculum. We make extensive use of online "self-learning modules" to prepare students for formal classroom activities. Our research on these online modules has identified successful characteristics to include learner control, adherence to instructional design principles in the use of visuals, and the inclusion of self-tests. When compared against segments of the curriculum without such online modules, student performance was shown to significantly increase (3).
Our classroom instruction emphasizes co-operative learning to leverage the purported acumen of Millennial students in this kind of learning. The use of team-based learning, case-based learning, simulations and other approaches where group work occurs has the overall goal of using classroom time to engage higher order learning. We have developed software to deploy virtual laboratory classes and also use ADInstruments LabTutor software to author and present case-based learning materials. In both cases students work in groups to solve problems and upload their collective solutions online, giving the opportunity for faculty feedback. Our qualitative research in this area suggests that students are highly accepting of the organizational structure and quality of content but also appreciate how the software supports group process, co-operative learning and that it allows self-monitoring (4). However, when comparing generic feedback to group-specific feedback we found a significant decline in student acceptance for this specific component.
Formative assessment provided during the learning process has long been considered an important component of curricula. The need for rich feedback is also a trait associated with Millennial students. We provide extensive formative assessment by giving not-for-credit online quizzes every week throughout the first two years in addition to self-testing embedded in online instructional materials and feedback about cases. Our research in this area shows that the degree of participation in voluntary quizzes is a good indicator of student success in summative assessment. Despite sharing this information with students during orientation, a significant fraction of students still opt not to take online quizzes in a timely manner. In an in-depth interview study we have discovered that fear of judgment, time management, quality of questions and quality of feedback are the major barriers to quiz use. Despite the availability of a lot of formative assessment we find that improving the quality of feedback remains a challenge to satisfy the present generation of students.

Use of the moodle platform to create an effective online learning site

B. Ramirez

University of Santiago, Santiago, Chile

Moodle is a platform for teaching, available free in the web. It can be used in totally virtual courses (e-learning) or as support in classic courses (b-learning). It offers multiple possibilities for interactive learning, since it supports wikis, forums, tests, data-bases and others, than can be accessed on line by the students. Teachers can also offer there a copy of the powerpoints and documents in different formats, to be accessed at all time by the students.
I will show here tips for using moodle both, for e-learning and for b-learning.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Strategic directions and collaborations for teaching physiology in the new millennium

P. Poronnik

School of Medical Sciences, The University of Sydney, Sydney, NSW, Australia

Physiology teaching in the new millennium is well placed to embrace not only the new technological affordances but also the significant paradigm shift that is emerging in the bioinformatics / systems biology revolutions. However, adapting to these changes means that we will have to revisit traditional academic roles.
In terms of technologies, MOOCs and classroom inversion are emerging as very real factors that will influence the way in which academics and students interact and require, in some instances, re-articulation of the purpose of a campus based experience. Mobile computing devices are also a clear game changer, a revolution in which we are already caught up. The new affordable and compact tablet PCs are the most recent player, bringing the capacity for each student to connect directly to and run sophisticated data acquisition equipment. This allows the student in effect to "own" the experiment and their data.
In the context of physiology teaching, the proliferation of mobile wireless personal monitoring devices as well as increasingly affordable genetic and proteomics screening are significant points of leverage. This rapid shift to personalized medical data gathering presents multiple opportunities for students to contextualize learning to themselves – making these data very authentic. One significant challenge is how best to position the core physiology content while optimizing student engagement. The possibility of having student cohorts collect large data sets opens up "cloud-sharing" to compare population parameters across local and national boundaries in new ways. This enables a deeper appreciation of how the cultural and environmental surrounds effect human physiology.
Gamification / augmented reality can also be powerful tools to enhance student learning when implemented in appropriate ways. Quality on-line resources such as laboratory modules, simulations and patient / case studies are also critical in the mobile world. Our students live, however, in a world of expecting high production values and achieving this comes with significant labour and cost implications.
We have already entered this very exciting era. It is the speed of change and our capacity to adapt to and resource these changes that are our greatest challenges. There is an urgency to develop strategies that connect the innovators and early adopters with the broader physiology community in a unity of purpose around the new ways of teaching.
The most effective means to facilitate a community approach is through the formation of collaborative leadership networks. Such networks can serve to (i) provide the critical mass needed to identify, address and solve the central challenges that face us in delivering a forward looking and sustainable curriculum and (ii) maximize the efficiency of development, dissemination and adoption of innovative physiology teaching. This critical mass is also essential to seek new the funding opportunities required to support innovation and sustainability. In a complex international environment, such a network can serve to aggregate, filter and connect ideas and information with the appropriate teams of people to achieve effective, transferable and sustainable solutions. There are some examples of local networks, however, these are issues that required collaboration at an international level. IUPS is well positioned to play a central role in such an extended network.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Experiences in using online courses

A.K. Vidanapathirana

Department of Physiology, University of Colombo, Colombo 8, Sri Lanka and Department of Physiology, Brody School of Medicine, East Carolina University, Greenville, NC, USA

With the advancement of e-learning, online instruction is becoming a significant component of graduate education. This presentation is based on experiences in the Professional Skills Training Online Course: Abstract Writing for Scientific Meetings conducted by the American Physiological Society. Insights gained following discussions with colleagues who followed several other online courses in various disciplines and in different formats are also included.
Online courses are more conducive in the global e-leaning environment. Compared to live courses covering similar material, the online courses have the unique advantages of being convenient, time and cost effective for both organizers and participants. The retention of knowledge through these online courses was largely dependent on the format of delivery, relevance and applicability. Well defined objectives and a tutorial on the course design with technical support at the beginning of the course greatly enhanced the knowledge gain. However, online only courses have the disadvantage of limited face-to face interactions and discussions which impedes the peer learning and professional interactions. The blended course design (i.e. a combination of live and online course components) was perceived as a more effective method of teach-

ing in the current graduate education. The overall efficiency of learning through online courses was determined by the course content, context, incentives and commitment of the participants. Students who are self-motivated and prefer a self-learning approach in contrast to didactic teaching benefit more from these courses.
The meticulous selection of topics and content is crucial in designing online courses as all subject matter and skills cannot be conveyed or conceived online. Expanding the opportunities for live interactions within the course will increase the overall appeal and success of online courses. The characteristics and the prerequisites of the target student population also need to be considered in designing, implementing and evaluating graduate level online courses. Well defined guidelines and measures of quality-control for online courses will greatly facilitate the sustainability of online education.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA56

Development and evaluation of online courses and resources

D. Dewhurst

Learning Technology, Edinburgh University, Edinburgh, UK

Physiology teaching has a history of being at the forefront in the use of technology-enhanced learning methods. This presentation will cover the use of technology-enhanced learning in physiology from multimedia CALs in the 1980s and 1990s, virtual learning environments, open educational resource initiatives and learning object repositories in the early 2000s, and more recently web-based courses delivered entirely online and Massive Open Online Course (MOOCs) initiatives.
Early use of technology in physiology teaching focused on learning materials such as multimedia resources, largely developed to support student-centred learning. Typically such resources made effective use of features such as high-quality graphics, animation, video and audio bringing a range of media together into a single package and delivering it on CDROM. Some were developed to support teaching of practical physiology providing students with activities and self-assessments built around data from laboratory experiments on either human or animal subjects. In a virtual laboratory students might sit at a computer and be required to 'design' experiments, collect data from the computer screen, analyse and report their results in much the same way as they would in the real laboratory. Built-in self-assessment questions would test accuracy of data collection, data interpretation skills and knowledge of underlying physiological principles. Students could use the virtual labs to better prepare themselves for a real laboratory teaching session or they might use them to collect additional data outside the laboratory session. In some instances the 'simulations' might replace a real laboratory session and this practice has become more common as the 'cost' of providing real laboratory experiences for students has increased. Other multimedia resources focused on supporting lectures, presenting factual information on specific topics and structuring this alongside student activities and self-assessments in an interactive format which went beyond the traditional textbook approach. Students would commonly have 24/7 access to such resources with tutors often embedding the resources into the curriculum. Numerous evaluations of the educational effectiveness of both virtual labs and interactive tutorials have been carried out, most suggesting that the computer-based learning materials can address many of the learning objectives very effectively, and data from some of these studies will be presented.
The last ten years has seen the growth of Internet resources many of which are openly accessible, some provided by institutions as 'open courseware', others provided by individuals. It is now possible for students to access teaching materials, e.g. an online video lecture, from a world expert on a particular topic; they have access to online textbooks, online wikis, e-books and more and more universities are putting their course content online. Teachers can now provide their students with prior access to a wide range of high-quality factual information, generated by themselves and/or others and utilize face-to-face teaching sessions in a more interactive way to, for example, diagnose learning difficulties, better explain curriculum topics which students find difficult, or contextualise the factual information through problem-based or scenario-based learning approaches. Audio-responses systems are often cited as an effective way of making such sessions more engaging and promoting peer learning. This 'flipped-classroom' approach has been found to be effective in supporting student learning. While there may be some questions around the quality of open-access resources there is little doubt that students will continue to use the web as their first port of call for factual information and we need to ensure that students are provided with resource discovery skills and the ability to properly critique and quality-assure those resources.
More recently some universities have started to offer online courses in which all student – tutor interactions take place online. These may be credit-bearing courses (e.g. University certificate, diploma or Masters degree), or they be short non-credit bearing courses, such as MOOCs, which typically offer certificates of completion rather than educational credits. There is no doubt that the flexibility such courses offer is highly beneficial to and highly valued by many learners particularly those in developing countries where access to high quality learning resources can be problematic for many. The presentation will look at some examples of online distance learning courses and MOOCs and give some institutional perspective of their development, sustainability and how they might be evaluated.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA57

Aging and DNA methylation: A role in fetal origins of adult disease?

C. Sapienza and S. Song

Fels Institute for Cancer Research, Philadelphia, PA, USA

Age-associated differences in site-specific DNA methylation have been observed in both humans and animal models. We, and others, have also observed longitudinal changes in DNA methylation in humans, with an average interval between samples of more than a decade. Our published data indicate that it is likely that both genetic and environmental factors are involved with these changes. The absolute magnitude of the observed changes in humans is small but, by extrapolation from data in the mouse, may be considerably larger in some tissues. Moreover, we have observed that even small differences in DNA methylation can be associated with much larger differences in transcript level. Nevertheless, whether such age-

related differences are a cause or a consequence of aging is a matter for discussion. Multiple epidemiological studies have identified maternal age as an additional factor influencing the longevity of offspring, with those offspring born to younger mothers living longer than offspring born to older mothers. We have examined site-specific DNA methylation in the offspring of mothers whose ages vary by more than 20 years. A number of genes exhibit maternal age-related differences in DNA methylation. Our observations indicate a potential role of maternal age-related methylation differences in the health and lifespan of offspring.

The ageing brain; effects on DNA repair and DNA methylation in mice

S.A. Langie[1,2], K.M. Cameron[3], G. Ficz[4], D. Oxley[4], B. Tomaszewski[2], J.P. Gorniak[2], L.M. Maas[5], R.W. Godschalk[5], F.J. van Schooten[5], W. Reik[4], T. von Zglinicki[3] and J.C. Mathers[2]

[1]Environmental Risk and Health unit, Flemish Institute of Technological Research (VITO), Mol, Belgium, [2]Centre for Brain Ageing and Vitality, Human Nutrition Research Centre, Institute for Ageing & Health, Newcastle University, Campus for Ageing and Vitality, Newcastle upon Tyne, UK, [3]Centre for Integrated Systems Biology of Ageing and Nutrition, Institute for Ageing and Health, Newcastle University, Campus for Ageing and Vitality, Newcastle upon Tyne, UK, [4]Laboratory of Developmental Genetics and Imprinting, The Babraham Institute, Cambridge, UK and [5]Department of Toxicology, Maastricht University, Maastricht, Netherlands

DNA repair systems such as base excision repair (BER) may become less effective with ageing resulting in accumulation of DNA lesions, genome instability and altered gene expression that contribute to cellular and tissue dysfunction and increase the risk of age-related degenerative diseases. The brain is particularly vulnerable to accumulation of oxidative DNA lesions and proper functioning of DNA repair mechanisms is thus important for neuronal survival. Although the mechanism(s) of age-related decline in DNA repair capacity is unknown, growing evidence suggests that epigenetic events, including aberrant DNA methylation, contribute to the ageing process and may be functionally important through dysreguledexpression of DNA repair genes.

We hypothesise that oxidative stress modulates DNA repair, specifically BER, in the ageing brain and that epigenetic mechanisms are involved in mediating age-related effects. Brains from C57/BL male mice were isolated at 3-32 months of age. Using pyrosequencing, we observed significantly increased methylation of the promoter region of the BER gene *Ogg1* with ageing, which correlated inversely with *Ogg1* expression. The reduced *Ogg1* expression correlated with enhanced expression of methyl-CpG binding protein 2 (MeCP2) and of ten-eleven translocation enzyme 2 (Tet2). The functional consequence, if any, of the latter association is unclear since Tet enzymes can convert 5-methylcytosine to 5-hydroxy-methylcytosine and play a role in further active DNA demethylation. On this basis, one would have anticipated an inverse correlation between expression of *Ogg1* and of *Tet2*. MeCP2 is a methyl-CpG binding protein that can suppress transcription. In adult brain, MeCP2 binds to methylated DNA across the genome and plays a crucial role in normal brain functioning. We also observed a significant inverse correlation between gene methylation and expression observed for *Neil1*, which is another BER gene. During ageing, there was a trend towards decreased expression of *Mutyh* and *Xrcc1*, in parallel to slightly higher gene methylation levels. The corresponding phenotype i.e. BER-related incision activity in brain was reduced significantly, which was associated with significantly increased 8-oxo-7,8-dihydro-2'-deoxyguanosine levels. These data indicate that *Ogg1* and *Neil1* expression can be epigenetically regulated and that this may play a role in the adverse effects of ageing on DNA repair in mammalian brain.

In conclusion, this study has provide evidence that through altered expression of BER genes, epigenetic mechanisms - i.e. increased promoter methylation as well as the involvement of TET enzymes and MeCP2 - can reduce capacity for neuronal DNA repair during ageing. This reduced capacity for DNA repair may contribute to the accumulation of oxidative DNA damage and mutations across the whole genome, causing genome instability and increasing the risk of age-related neurodegenerative diseases.

The Centre for Brain Ageing & Vitality is funded through the Lifelong Health and Wellbeing cross council initiative by the MRC, BBSRC, EPSRC and ESRC. This work was further supported by the Centre for Integrated Systems Biology of Ageing and Nutrition funded by the BBSRC and EPSRC. We thank Hoffmann-La Roche (Basel) for supplying Ro 19-8022 and Sofia Lisanti for providing us the primer sequences for the qRT-PCR reference genes. We also like to thank Adele Kitching, Satomi Miwa, Liz Nicolson and Julie Wallace for care of the animals and assistance with dissections.

Genome-wide epigenetic changes during ageing

M.F. Fraga

IUOPA, Universidad de Oviedo, Oviedo, Spain

Genomic DNA methylation is not stable during development and aging. Recent works, mainly focused in blood, show that DNA hypermethylation in aging preferentially occurs at sequences associated with bivalent chromatin domains in embryonic stem cells that are also frequently hypermethylated in cancer. In my talk, I will comment recent work of our laboratory in which we compare the genome wide DNA methylation status of adult stem cells obtained from healthy individuals of different ages. Using this approach we identified a set of genes showing specific DNA methylation changes in aged stem cells. In addition, by crossing these genes with previously published genome-wide data on chromatin modifications, we identified a global epigenetic signature of aging.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA60

Epigenetic regulation of retrotransposable elements by TET enzymes

M. Branco

Epigenetics Programme, The Babraham Institute, Cambridge, UK and Centre for Trophoblast Research, University of Cambridge, Cambridge, UK

DNA methylation or 5-methylcytosine (5mC) is crucial for embryonic development and plays important roles in the control of gene expression, genome stability and silencing of transposable elements. It was recently shown that the TET family of enzymes can oxidize 5mC to 5-hydroxymethylcytosine (5hmC) as part of a potential demethylation pathway. We and others have shown that TET1 and 5hmC help to maintain the pluripotency network in mouse embryonic stem (ES) cells by preventing methylation of pluripotency-associated genes. We also found that LINE1 retrotransposons are enriched for 5hmC at their 5' end in ES cells and more recently confirmed this using a quantitative technique for single-base mapping of 5hmC. TET targeting to LINE1 elements maintains them in a hypomethylated state and consequently transcriptionally active. TET enzymes may therefore be involved in controlling retrotransposon mobility and thus implicated on the impact that these potentially mutagenic elements have on the genome. We are currently investigating the role of these epigenetic mechanisms in controlling LINE-1 mobility in ES cells, neural stem cells and during ageing, where increased retrotransposon mobility may contribute to the etiology of neurodegenerative diseases.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA61

Epigenetic regulation of fetal growth and healthy aging

R. John and S. Tunster

Cardiff, Cardiff, UK

A defining feature of mammals is the development in utero of the fetus supported by the constant flow of nutrients from the mother (John and Hemberger, 2012). Poor growth in utero combined with rapid post natal catch up growth is known to predispose to the development of metabolic diseases in adult humans, including type 2 diabetes. A significant proportion of human low birth weight infants exhibit elevated placental expression of the imprinted PLECKSTRIN HOMOLOGY-LIKE DOMAIN, FAMILY A, MEMBER 2 (PHLDA2/IPL/TSSC3) gene (McMinn et al., 2006).
We have engineered this specific alteration in a mouse model system and found that elevated expression of Phlda2 drives severe placental defects alongside asymmetrical fetal growth restriction (Tunster et al., 2010). The low birth weight offspring rapidly catch up growth with their littermates but develop glucose intolerance and show increased adiposity as adults. Using another genetic model, we are able to rescue both fetal growth restriction and glucose intolerance thus assigning the adult phenotypes to the in utero growth restricting properties of Phlda2. We are also able to demonstrate that Phlda2 is a nutrient responsive gene in the placenta. These data support the idea that factors manipulating epigenetic processes early in life can influence the aging process. Furthermore, our data suggest that low birth weight human infants with high PHLDA2 expression may be predisposed to develop type 2 diabetes and other diseases linked to fetal programming.

SA62

Regulation of ENaC by external cues

T. Kleyman

Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Epithelial Na channels (ENaCs) reside in the apical membrane of principal cells in the aldosterone-sensitive distal nephron, where they transport Na and have key roles in extracellular volume homoeostasis and blood pressure control. Specific proteases activate ENaC, a trimer composed of three structurally related subunits, by liberating inhibitory tracks imbedded in the extracellular regions of the alpha and gamma subunits. Extracellular Na inhibits ENaC by binding to sites within the extracellular regions of ENaC subunits, leading to a reduction in channel open probability. Recent findings regarding sites within ENaC subunits where inhibitory peptides and Na bind, and how these binding events affect channel gating will be reviewed.

Support by grants from NIDDK.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Activation of the epithelial sodium channel by plasmin and cathepsin-S

S. Haerteis, M. Krappitz, A. Diakov, A. Krappitz, R. Rauh and C. Korbmacher

Institut für Zelluläre und Molekulare Physiologie, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

Proteolytic channel activation is a unique feature of the epithelial sodium channel (ENaC). Cleavage at specific sites in the extracellular domains of α-, δ-, and γENaC is essential for channel activation [1; 2]. However, the (patho-)physiologically relevant proteases and molecular mechanisms involved in proteolytic channel activation remain to be determined. Inappropriate ENaC activation by proteases may be involved in sodium retention and the pathogenesis of arterial hypertension in the context of renal disease. Recently, we and others reported that the serine protease plasmin can proteolytically activate ENaC which may contribute to renal sodium retention in nephrotic syndrome [3; 4]. In mouse γENaC a puta-

tive plasmin cleavage site (K194) has been reported [4]. For human ENaC, the relevant cleavage site(s) for plasmin remain to be determined. In addition to serine proteases, cathepsin proteases may activate ENaC. Cathepsin proteases belong to the group of cysteine proteases and play a pathophysiological role in inflammatory diseases. Under pathophysiological conditions cathepsin-S (Cat-S) may reach ENaC in the apical membrane of epithelial cells. Our aims were (a) to identify functionally relevant plasmin cleavage sites in human γENaC [5] and (b) to investigate the effect of Cat-S on human ENaC [6].

Mutant human γENaC constructs were generated by site-directed mutagenesis. Human wild-type or mutant αβγENaC was expressed in *Xenopus laevis* oocytes. Amiloride-sensitive whole-cell currents (ΔI_{ami}) were determined by two-electrode voltage-clamp before and after 30 min incubation of the oocytes in human plasmin (10 μg/ml), chymotrypsin (2 μg/ml) or Cat-S (1 μM). Biotinylated cell surface γENaC cleavage products were detected by western blot analysis using a γENaC antibody.

(a) Sequence alignment revealed a putative plasmin cleavage site in human γENaC (K189) that corresponds to a plasmin cleavage site (K194) in mouse γENaC. We mutated this site to alanine (K189A) and expressed human wild-type αβγENaC and αβγK189AENaC in oocytes. The γK189A mutation reduced but did not abolish activation of ENaC whole-cell currents by plasmin. Mutating a putative prostasin site (γRKRK178AAAA) had no effect on the stimulatory response to plasmin. In contrast, a double mutation (γRKRK178AAAA;K189A) prevented the stimulatory effect of plasmin. We conclude that in addition to the preferential plasmin cleavage site K189 the putative prostasin cleavage site RKRK178 may serve as an alternative site for proteolytic channel activation by plasmin. Interestingly, the double mutation delayed but did not abolish ENaC activation by chymotrypsin. The time-dependent appearance of cleavage products at the cell surface nicely correlated with the stimulatory effect of chymotrypsin on ENaC currents in oocytes expressing wild-type or double mutant ENaC. This indicates a causal link between proteolytic cleavage and channel activation. Delayed proteolytic activation of the double mutant channel with a stepwise recruitment of so-called near silent channels was confirmed in single-channel recordings from outside-out patches. Interestingly, mutating two phenylalanines (γFF174) adjacent to the prostasin cleavage site prevented proteolytic activation by chymotrypsin. This indicates that the two phenylalanines constitute a preferential cleavage site for ENaC activation by chymotrypsin.

(b) We demonstrated that Cat-S activates ΔI_{ami} in ENaC-expressing oocytes. ENaC stimulation by Cat-S was associated with the appearance of a γENaC cleavage fragment at the plasma membrane indicating proteolytic channel activation. Mutating two valine residues (V182 and V193) in the critical region of γENaC prevented proteolytic activation of ENaC by Cat-S. The stimulatory effect of Cat-S on ENaC activity and the concomitant appearance of a γENaC cleavage product at the cell surface were prevented by the Cat-S inhibitor LHVS (morpholinurea-leucine-homophenylalanine-vinylsulfone-phenyl). In contrast, LHVS had no effect on ENaC activation by the prototypical serine proteases trypsin and chymotrypsin. To our knowledge, this is the first report that the cysteine protease Cat-S can activate ENaC which may be relevant under pathophysiological conditions.

In this study, we identified cleavage sites in a region critical for proteolytic channel activation in the γ-subunit of human ENaC with functional importance for its proteolytic activation by plasmin, chymotrypsin and Cat-S. The fact that γENaC contains several different cleavage sites in this region is likely to have physiological implications. Indeed, it may provide a mechanism for differential ENaC regulation by tissue-specific proteases.

Regulation of the epithelial Na^+ channel (ENaC) by kinases

A. Dinudom, I. Lee, S. Song and D.I. Cook

Discipline of Physiology, Sydney Medical Scool, The University of Sydney, Sydney, NSW, Australia

Activity of the amiloride-sensitive Na^+channel (ENaC) expressed in the distal nephron and respiratory epithelium has a profound impact on Na^+ homeostasis, the regulation of blood pressure and respiratory surface fluid volume. Dysfunction of ENaC underlies human diseases such as Liddle's syndrome, pseudohypoaldosteronism type 1 and cystic fibrosis. The activity of ENaC is tightly controlled by an array of physiological factors that exert their effect on transcription, trafficking and gating of the channel via multiple cellular signalling pathways. Hydrogen peroxide (H_2O_2) is one of the reactive oxygen species produced in response to oxidative stress, and it modulates a variety of physiological events. H_2O_2 exerts its effects via redox-sensitive proteins including transcription factors, protein tyrosine kinases and small G proteins. Previous studies suggested that H_2O_2 plays an important role in the regulation of ENaC, implicating it in the pathophysiology of pulmonary edema and acute lung injury. Consistent with this notion, exogenous H_2O_2 inhibits transepithelial ion transport and suppresses baseline expression of the α-subunit of ENaC in alveolar epithelial cells. In agreement with these reports, we found that H_2O_2 has a profound inhibitory effect on the amiloride-sensitive current in mouse collecting duct (M1) cells and on exogenous ENaC expressed in Fisher Rat Thyroid (FRT) cells. This inhibitory effect of H_2O_2 is attenuated in cells over-expressing a dominant-negative mutant of apoptosis signal-regulating kinase 1 (ASK-1), a ubiquitously expressed MAP kinase kinase kinase that is activated in response to cytotoxic stress. Our data further suggest that H_2O_2 inhibits the activity of ENaC via the ASK-1/p38 MAP kinase signalling cascade by a mechanism that interferes with proteolytic activation of ENaC subunits. H_2O_2 is also known to be an activator of the proto-oncogene tyrosine-protein kinase (Src), a non-receptor membrane-associated tyrosine kinase that plays an important role in cytoskeletal organization and cell proliferation, tyrosine phosphorylation of many cellular signalling molecules and is involved in the cellular signalling pathway by which endothelin-1 inhibits activity of ENaC. We found that Src mediates the inhibitory effect of platelet-derived growth factor (PDGF) on ENaC. Unlike ASK-1, Src alters total ENaC protein expression and the abundance of ENaC at the

cell membrane, but has no effect on proteolytic cleavage of the channel subunits. The inhibitory effect of Src requires caveolin-1, suggesting that the effector molecules that are involved in the Src-mediated signalling system that regulates ENaC may be organised in the cholesterol-rich lipid raft sub-membrane domain.

Multiple COMMD proteins alter the trafficking of the epithelial sodium channel, ENaC

F.J. McDonald[1], Y. Liu[1], M. Swart[1], K. Ly[1] and E. Burstein[2]

[1]Physiology, University of Otago, Dunedin, New Zealand and [2]Internal Medicine and Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX, USA

The epithelial sodium channel (ENaC) has an important role in maintaining salt and water balance, and in long-term blood pressure control. Multiple proteins interact with ENaC to control its forward movement along the protein secretion pathway to the cell surface, and ENaC endocytosis and trafficking to the lysosome or recycling endosome (reviewed in Butterworth 2010). For example, the E3 ubiquitin ligase Nedd4-2 catalyses covalent attachment of ubiquitin moieties onto ENaC subunits to promote endocytosis and trafficking to the lysosome. Nedd4-2 action is mitigated upon its phosphorylation by the aldosterone-stimulated kinase SGK1. The regulation of ENaC in the kidney by Nedd4-2 and SGK1 appears to be a key pathway by which ENaC Na+ transport is controlled. We discovered that the Copper Metabolism Murr1 Domain-containing protein 1 (COMMD1) interacts with ENaC (Biasio et al., 2004), and reduces amiloride-sensitive short circuit current (Isc-amil) in Fischer rat thyroid (FRT) epithelia expressing ENaC. COMMD1 appears to form a complex with SGK-Nedd4-2 resulting in a decrease in the ENaC population at the cell surface (Ke et al., 2010). COMMD1 is the founding member of a ten-member family of proteins (COMMD1-10) sharing a C-terminal COMM domain (Burstein et al., 2005). Although COMMD1 has pleiotropic roles in copper, chloride transport, NF-κB transcriptional downregulation, and regulation of the HIF1α complex, roles for other COMMD proteins have not been described. To investigate whether other COMMD proteins also regulate ENaC we used co-immunoprecipitation and showed that COMMD1-10 all interact with ENaC. Using immunohistochemistry we found that COMMD1, 3, and 9 were widely expressed in rat kidney including collecting duct cells, and showed colocalisation with ENaC. COMMD1, 3, and 9 individually inhibited Isc-amil in ENaC-expressing FRT epithelia. These COMMD proteins appear to have unique roles in inhibiting ENaC because COMMD3 and 9 retained their ability to reduce Isc-amil in ENaC-expressing FRT epithelia when COMMD1 expression was reduced using siRNA knockdown. COMMD1, 3, and 9 all decreased cell surface expression of ENaC, therefore they likely affect trafficking of ENaC to or from the cell surface. Another family member, COMMD10, was found to regulate forward trafficking of proteins in the secretory pathway. Thus multiple COMMD family members negatively regulate ENaC, but may act at different locations in the protein trafficking pathway.

***In vivo* regulation of ENaC by the ubiquitin ligase Nedd4L in lung and intestinal epithelia**

D. Rotin

Hospital for Sick Children, Toronto, ON, Canada

The amiloride-sensitive Epithelial Na+ Channel (ENaC) plays a pivotal role in regulating salt and fluid transport in salt absorbing epithelia in the kidney, lung, intestine and other tissues, and is involved in controlling blood pressure. An important regulator of ENaC stability at the plasma membrane is the ubiquitin ligase Nedd4L (Nedd4-2), which promotes ENaC ubiquitination and endocytosis, thus downregulating the channel by targeting it for lysosomal degradation. In vivo, knockout of Nedd4L in mouse kidney was shown (by the Staub and Yang groups) to increase abundance of both ENaC and the Na+/Cl- co-transporter, leading to salt-induced hypertension. The in vivo role of Nedd4L in the lung was not known. To investigate the role of Nedd4L in the lung, we knocked it out specifically in lung epithelia (in SPC-expressing Type II and airway epithelial cells). Our results show that these mice developed cystic fibrosis-like lung disease, with airway mucus obstruction, goblet cell hyperplasia, massive inflammation, fibrosis and death by 3-weeks of age. Cystic fibrosis is caused by impaired ion transport due to mutated CFTR, accompanied by elevated activity of ENaC. These effects of Nedd4L loss in the lung were likely caused by enhanced ENaC function, as reflected by increased ENaC protein levels, increased lung dryness at birth, amiloride-sensitive dehydration of lung explants, and elevated ENaC currents in primary alveolar-Type II cells analyzed by patch clamp recordings. Moreover, the lung defects could be rescued with administration of amiloride into the lungs of young knockout pups via nasal instillation. Our results therefore suggest that the ubiquitin ligase Nedd4L normally opposes the onset of cystic fibrosis symptoms by inhibiting ENaC in lung epithelia. More recently, we have begun investigating the role of Nedd4L in the intestine, by knocking out Nedd4L specifically in intestinal epithelium (in Villin-expressing cells). The results of these studies will be presented.

Human and small animal studies of maternal obesity and weight gain

L. Poston

Women's Health, King's College London, London, UK

Mother-child cohort studies suggest an association between maternal BMI/ excessive gestational weight gain and offspring risk of cardiovascular and metabolic disease. Investigations are however complicated by inevitable confounding influences of postnatal factors which cannot always be accounted for in statistical analysis, and assumption of causality must be cautious.Randomised controlled trials (RCTs) of intervention studies in pregnant women which aim to ameliorate the metabolic influences of maternal obesity on the developing child can obviate some of these issues. The EU funded EarlyNutrition project brings together several relevant RCTs to address the influence of maternal interventions on childhood obesity and health, including the UK UPBEAT trial of a complex (dietary and physical activity) intervention in obese pregnant women. Protocols have been standardised between studies, and children will be investigated at the age of 3 and 5. Detailed measurement of body composition, breast feeding history, diet, and physical activity, as well as health, social and environmental factors will be obtained. With knowledge the maternal body composition, weight, diet and physical activity from women in intervention and control arms of the studies, these studies should provide valuable information on maternal/child obesity relationships, as well as other childhood health outcomes. Mechanistic insight will also be gained but for practical reasons this cannot be of equivalent depth to that achievable in animal models, which have provided convincing evidence for influences of maternal obesity on offspring health. Models of maternal obesity in rodents, performed under UK Home Office legislation have provided information on the mechanisms leading to offspring obesity and hypertension in the offspring, including a central role for hypothalamic centres of energy balance and autonomic pathways of blood pressure control. The offspring also demonstrate a hepatic disorder very similar to non-alcoholic fatty liver in man. These studies have led to testable hypotheses in the children of obese women, which we have now incorporated into studies of children in a mother-child cohort study (SCOPE) and from the UPBEAT trial.

Offspring of mothers on a high fat diet show altered circadian biology and fatty liver

K.D. Bruce[1,2], D. Szczepankiewicz[2], K.K. Sihota[2], M. Ravindraanandan[2], M.A. Hanson[2], C.D. Byrne[2] and F.R. Cagampang[2]

[1]Metabolism and Aging, The Scripps Research Institute, Jupiter, FL, USA and [2]Human Development and Health, University of Southampton, Southampton, Hampshire, UK

Perturbations in circadian rhythms are associated with a range of metabolic disorders including obesity, type 2 diabetes and fatty liver disease. We have previously shown that high fat (HF) exposure during early life primes adult onset of severe fatty liver in the offspring. Recent findings show that hepatic lipid homeostasis is maintained by a cell autonomous transcriptional feedback loop composed of the transcription factors CLOCK and BMAL1 and their target genes many of which are transcription factors with roles in lipogenesis (e.g REVERB, SREBP1c). Therefore, the precise timing of clock gene expression is critical for optimal hepatic metabolism. The "clock" proteins are regulated by the NAD+ dependent deacetylase SIRT1, and thus are themselves influenced by nutrition and cellular metabolism. To date, the effect of HF exposure during early life on the circadian clock network and hepatic metabolism in the offspring in later life is unknown. We used our mouse model of developmentally primed fatty liver disease to demonstrate that offspring exposed to HF diets during development and adulthood exhibit the most severe fatty liver phenotype in later life. These offspring also show a reduction in cellular NAD+ and SIRT1 expression. We show that the circadian pattern of core clock genes, and protein expression, is disrupted in response to a HF diet a perturbation that is exacerbated in offspring exposed to a maternal HF diet during development. Moreover, expression of clock target genes involved in lipogenesis (REVERB, SREBP1c) is up-regulated in offspring from HF fed mothers, which may further contribute to fat accumulation in the liver. Our results suggest that early HF exposure causes persistent changes in cellular redox status, SIRT1 reduction, clock gene imbalance, and up-regulated lipogenic transcription factors, developmentally priming the onset of fatty liver in later life.

Programming metabolic and psychological diseases: effects of maternal obesity and diet

K. Grove

ONPRC/OHSU, Beaverton, OR, USA

Childhood obesity is associated with increased risk of metabolic diseases later in life; however, it is also associated with a broad spectrum of behavior/psychological disorders including depression, anxiety, poor learning, and attention deficient disorder. Maternal obesity, diabetes and high fat diet (HFD) consumption during pregnancy, which is highly prevalent in the United States, has a high association with early onset obe-

sity. Using a nonhuman primate (NHP) model our group is investigating the relative impact of maternal metabolic health and diet on the development of hypothalamic systems involved in the regulation of energy homeostasis as well as stress and anxiety behaviors. To date, we have observed that fetal offspring of animals consuming the HFD develop early onset fatty liver as well as abnormalities in the development of pancreatic islets and in brain circuits involved in the regulation of appetite and stress responsiveness. A likely causal factor for these developmental abnormalities is placental insufficiency and an increase in circulating cytokines (originating from the placenta) during critical periods of fetal development, as well as the activation of local inflammatory systems within the brain. Importantly, most of these developmental programming effects were independent of the maternal metabolic phenotype, as they were observed in both obese and lean animals consuming the HFD. Infant offspring of animals consuming the HFD have a higher rate of growth during the postnatal period resulting in a doubling of body fat and insulin resistance, as well as pancreatic islet hyperplasia and fatty liver at weaning. Furthermore, female, but not male, infant offspring also display increased anxiety-like behavior. This sexual dimorphism in anxiety-like behavior is consistent with human clinical studies demonstrating that the behavior/psychological disorders associated with childhood obesity are more prevalent in young girls. However, both male and female HFD offspring displayed increased appetite, food preferences for palatable foods and social behavior abnormalities, that were not reversible by post-weaning diet reversal. Overall, these results suggest that chronic consumption of a HFD during pregnancy alone can cause significant abnormalities in the development of critical metabolic system in the fetal offspring. Many of the changes appear to be due to the high lipid environment leading to the activation of the proinflammatory cytokines both within the placenta as wells as the brain. This lipotoxicity may also have broad negative impact on the neural systems involved in social behavior as well as learning and memory.

[1]Sansom Institute for Health Research, School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, SA, Australia, [2]Discipline of Physiology, School of Molecular and Life Sciences, University of Adelaide, Adelaide, SA, Australia, [3]Institute of Metabolic Science-Metabolic Research Laboratories, University of Cambridge, Cambridge, UK and [4]Turretfield Research Centre, South Australian Research and Development Institute, Rosedale, SA, Australia

The obesity epidemic has resulted in more women entering pregnancy overweight or obese. Offspring of obese women have increased risk of obesity and impaired glucose tolerance in childhood and adult life. It has therefore been proposed that there is an 'intergenerational cycle' of obesity and insulin resistance. Studies have shown that changes in the abundance of insulin signalling molecules in skeletal muscle and adipose tissue precede the development of insulin resistance and type 2 diabetes (1,2). It is not clear, however, whether exposure to maternal obesity results in insulin resistance in her offspring as a consequence of the impact of increased adiposity on insulin sensitive tissues (3,4) or as a consequence of the programming of specific changes in the abundance of insulin signalling molecules in these tissues (2,5). It has previously been shown in sheep that exposure to maternal obesity around the time of conception alone led to increased adiposity in female lambs at 4 months of age and that dietary restriction in the obese ewe during the periconceptional (PC) period abolished this effect (6). While dieting before pregnancy may have metabolic benefits for the offspring, there are also potential metabolic and endocrine costs for the offspring (7). The pathways and critical periods during which the metabolic consequences of maternal obesity or dietary restriction are transduced from mother to the offspring are, however, not known. Moreover, there is a paucity of knowledge on the possible epigenetic mechanisms that are recruited in the oocyte/early embryo, which could contribute to such changes.

We used an embryo transfer model in sheep to investigate the effects of maternal obesity and of dietary restriction during the PC period on insulin signalling in liver and skeletal muscle of the offspring. Furthermore, we also investigated the role of miRNAs in regulating hepatic insulin signalling in these offspring. Donor ewes were allocated to 1 of 4 groups & were fed the following diets in the PC period: 100% metabolisable energy requirements (MER) for ≥ 20wks (CC); 100% MER for ≥ 16wks & then 70% MER for 4wks (CR); ~180% MER for ≥ 20wks (HH); ~180% MER for ≥ 16wks & then 70% MER for 4wks (HR). This continued for 1wk post-conception before single embryos were transferred into recipient ewes of normal weight. At 16wks after birth, liver and skeletal muscle samples were collected to determine insulin signalling gene expression (by qRT-PCR) and protein abundance (by Western Blotting) and expression of key miRNAs (by qRT-PCR) in the offspring. The effects of PC nutrition and sex on protein abundance and miRNA expression were determined using a two-way ANOVA. A Duncan's post hoc test was used to determine significant differences between groups.

We found decreased insulin receptor (IR) ($P<0.05$), Akt2 (female lambs) ($P<0.05$), phospho-Akt ($P<0.01$) and phospho-FoxO1 ($P<0.01$) abundance and in contrast, an increased Caveolin-1 ($P<0.05$) abundance in the liver of HH lambs. There was a parallel increase in miR-29b ($P<0.05$), miR-103 ($P<0.01$) and miR-107 ($P<0.05$) expression in these lambs. Maternal dietary restriction abolished some of the effects of maternal obesity. The abundance of Akt2, however, remained low (female lambs) and Caveolin-1 and miR-103 remained increased in HR lambs. Furthermore, there was decreased hepatic PDK1 gene expression ($P<0.01$) and phospho-PDK1and aPKCζ protein abundance ($P<0.05$) in CR and HR lambs. In contrast to the liver, maternal obesity resulted only in decreased GLUT4 abundance in muscle of female lambs. There was, however, increased IR abundance and decreased aPKCζ, phospho-AS160 and GLUT4 abundance in both CR and HR lambs.

We have found that exposure of the oocyte/early embryo to maternal obesity leads to differential changes in gene expression and protein abundance of key insulin signalling molecules in liver and muscle in postnatal life. Our results also suggest that miRNAs may be potential epigenetic regulators that are sensitive to programming by the maternal metabolic/nutritional environment and may play a key role in transducing the metabolic consequences of maternal obesity from the mother

to her offspring. Importantly, we also found that in most instances, dietary restriction was unable to ablate the effects of maternal obesity in both liver and skeletal muscle of lambs. Instead, exposure to dietary restriction itself irrespective of whether the ewes were previously on a normal or high plane of nutrition led to changes in a different suite of molecules within both liver and skeletal muscle of the offspring. These results suggest that maternal metabolic response to weight loss around conception, irrespective of her pre-pregnancy body weight has long lasting metabolic consequences for the offspring, which may contribute to the emergence of insulin resistance in later life.

Role of muscle afferents in the ventilatory and circulatory response to endurance exercise

M. Amann

Department of Medicine, University of Utah, Salt Lake City, UT, USA

Ventilatory and cardiovascular responses to exercise are primarily regulated by two largely separate systems. The first, a feed-forward mechanism termed 'central command', elicits cardiovascular and ventilatory responses to exercise. The second, a feedback mechanism, reflexly changes ventilation and circulation as a consequence of limb muscle contraction. The focus here is on the latter.

Numerous animal and human studies have suggested a key role for muscle afferents in evoking cardiovascular and ventilatory responses during exercise. Specifically, non-nociceptive Group III/IV muscle afferents, the so-called 'ergoreceptors', are thought to depict the afferent arm of the cardiovascular and ventilatory reflexes, which are mediated via neural circuits in the nucleus tractus solitarius and the ventrolateral medulla. Recent human studies using local anaesthetics (lumbar epidural space) to block the central projection of Group III/IV muscle afferents during whole-body endurance exercise (leg cycling) found attenuated, similar or even increased cardiovascular and ventilatory responses when the identical exercise was performed with blocked muscle afferents. Although some of these studies conform to the idea that continuous afferent feedback is necessary for adequate ventilatory and circulatory responses, others are contradictory, leaving the exact role of muscle afferents in the cardioventilatory control during endurance exercise controversial. At least some of these conflicting findings may be explained by the use of local anaesthetics, which attenuate efferent as well as afferent nerve activity. The effects of local anaesthetics on efferent nerves cause a drug-induced 'muscle weakening', which inevitably requires an increase in central command in order to work at and/or maintain a given external workload. More recent studies designed to circumvent the confounding impact of local epidural anaesthetics now provide valuable insights into the effects of muscle afferents on the circulatory and ventilatory response to whole-body endurance exercise. By using lumbar intrathecal fentanyl, a selective μ-opioid receptor agonist, we were able to inhibit the central projection of Group III/IV muscle afferents without affecting the muscle's force-generating capacity and therefore without affecting central command during the exercise. The outcome of these studies clearly shows that when Group III/IV muscle afferents from the lower limbs are blocked during endurance exercise of various intensities, ranging from mild to heavy, circulation and pulmonary ventilation are substantially compromised. This not only causes arterial hypoxaemia and attenuates both perfusion pressure and blood flow, which eventually reduces O2 delivery to the working muscles, but also facilitates ventilatory and metabolic acidosis, all of which combine to accelerate the development of peripheral locomotor muscle fatigue during exercise. These findings suggest that continuous sensory feedback from working skeletal muscle may depict a vital component in providing a high capacity for rhythmic endurance exercise because controlled muscle perfusion and O2 delivery determine the fatigability of skeletal muscle and thus affect its performance.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA73

Separating central command, muscle mechano and metaboreflex mediated cardiorespiratory responses to exercise in man

L.C. Vianna

Physiology and Pharmacology, Fluminense Federal University, Niterói, Rio de Janeiro, Brazil

The cardiovascular and hemodynamic adjustments to exercise are primarily mediated by alterations in parasympathetic and sympathetic neural activity. These changes in autonomic neural outflow are mediated via three distinct neural control mechanisms: central command, exercise pressor reflex (EPR) and the arterial baroreflex. Central command is a feedforward mechanism that, through signals originating in higher brain centers, activates cardiovascular and somatomotor systems in parallel. The EPR is a feedback peripheral neural drive originating in skeletal muscle. The arterial baroreflex provides further modulation via tonically active baroreceptors, located in the carotid and aortic arteries. As such, the alterations in autonomic outflow during physical activity are carefully controlled by these neural inputs to induce changes in heart rate, stroke volume and total peripheral resistance and evoke increases in arterial blood pressure (BP) appropriate for the metabolic demands of the exercising muscle. Although all three neural

mechanisms are important for cardiovascular regulation during exercise, considerable attention has been given to the EPR due to its importance determining the magnitude of sympathoexcitation during exercise. The sensory component of the EPR is comprised of group III and IV skeletal muscle afferents that respond to both mechanical (i.e., muscle mechanoreflex) and metabolic (i.e., muscle metaboreflex) stimuli. It should be noted, however, that both type III and IV afferents show a degree of polymodality and may readily respond to either mechanical or metabolic provocation. The muscle mechanoreflex can be activated by mechanical stretch in humans, however its effects on cardiovascular responses appear small and transient. As a result, the evoked hemodynamic consequences to passive stretch of leg or arm muscles are limited in humans. In contrast, the muscle metaboreceptors are paramount in generating the reflex increases in sympathetic outflow during isometric exercise in normal physiological states. In humans, muscle metaboreflex activation can be isolated by means of circulatory arrest of the active limb just before the cessation of exercise. During this maneuver, metabolic by-products of muscle contraction are trapped in skeletal muscles and stimulate metabolically sensitive afferents fibers. Stimulation of these afferents results in an elevated blood pressure achieved in part by sympathetically-mediated increases in systemic vasoconstriction, with elevations in heart rate playing a minor role. Importantly, this maneuver isolates the muscle metaboreflex from central command and muscle mechanoreflex. Overall, while it is well established that the EPR is one of the principal mediators of the cardiovascular response to exercise, the receptors activating the group III and IV fibers that are important to EPR function remains unclear. Recent animal studies have reported that either capsaicin balm or infusion of capsazepine attenuates the pressor response to muscle contraction, indicating the transient receptor potential vanilloid1 (TRPv1) receptor (localized on the group IV afferent neuron) as an important mediator of the EPR via its metabolic component (named muscle metaboreflex). Whether these findings can be extended to human remains to be determined. Based on humans studies performed in our laboratory, I will provide evidence that capsaicin-based analgesic balm effectively attenuates BP (photoplethysmography), sympathetic outflow (peroneal microneurgraphy) and vasconstrictory (Doppler Ultrasound) responses evoked by metabolically sensitive skeletal muscle afferents in humans. These data are consistent with the concept that TRPv1 receptors contribute to the EPR in humans, via its metabolic component.

Spinal control of human inspiratory motoneurones

S. Gandevia[2,1], A. Hudson[1,2] and J. Butler[1,3]

[1]University of New South Wales, Neuroscience Research Australia, Randwick, NSW, Australia, [2]University of New South Wales, Neuroscience Research Australia, Randwick, NSW, NSW, Australia and [3]University of New South Wales, Neuroscience Research Australia, Randwick, NSW, Australia

Evolution is certain to have ensured optimal strategies to drive inspiratory muscles to produce pulmonary ventilation, a function which is essential for survival. However, the neural underpinnings for such strategies are little studied. We have examined the recruitment of single human motoneurones in obligatory inspiratory muscles, particularly the diaphragm and inspiratory intercostal muscles (e.g. Butler & Gandevia, 2008), in an attempt to find common strategies that may underlie their recruitment in different tasks. These include volitionally-driven inspiration and inspiration driven by chemical drive, presumably from pontomedullary respiratory centres.

During quiet breathing, inspiratory activity in the parasternal intercostal muscles is measured for populations of single units. There is earlier and greater activity in those muscle portions with a greater mechanical advantage for inspiration (e.g. De Troyer et al 2005; Gandevia et al 2006). This ensures efficient matching between neural drive and ventilation. This principle of 'neuromechanical matching' represents a recruitment strategy superimposed on the well-known Henneman size principle. During highly volitional breathing this strategy is preserved in the intercostal muscles (Hudson et al 2011). We have proposed that this common neuromechanical matching is mediated at a premotoneuronal level via a 'spinal distribution network' for inspiratory drive. Unfortunately, the human studies do not reveal whether such a network exists at a spinal level, or whether pontomedullary, or even motor cortical circuits are involved. However, recent studies in dogs spinalised at C2 show that intercostal motor unit firing preserves the usual neuromechanical matching of spontaneous breathing even when ventilation is evoked by thoracic spinal cord stimulation (DiMarco & Kowalski, 2010; 2011). This represents evidence for a spinal distribution network which can impose neuromechanical matching on intercostal motor output. There is also other evidence for respiratory propriospinal neurones (e.g. Saywell et al 2011). A spinal distribution network makes sense from an evolutionary perspective: axial muscles would first have been driven by reticulospinal paths, then also by bulbospinal paths as lung breathing developed, and then finally by corticospinal paths. Such a network would ensure efficient muscle use with a range of descending drives for different tasks.

Central and peripheral contributions to tremor – essentially we don't know

M. Lakie

University of Birmingham, Birmingham, UK

Pubmed shows that the annual total of papers mentioning physiological tremor has grown steadily from ~ 200 to ~ 400 over the last twenty years. One particular interest is the idea that a centrally generated, approximately 10 Hz component plays an important role in tremor generation. The concept of an autonomous central "tremor generator" is nearly as old as the discovery of the alpha rhythm. The discovery of a brain rhythm which had about the same frequency as tremor lead quickly to the idea that it "must" be the cause. This was quickly shown to be false, but the idea of a central generator is persistent. Work by Elble and colleagues established the central tremor generator ("an oscillating system of neurones located within the CNS", Elble and Koller (1990)). It is now common to divide tremor into "central" and "mechano-reflex" components. More recently, the central oscillator theory has been invoked to explain the approximately 10 Hz tremor-like discontinuities that can be observed during movement (for example, Vallbo and Wessberg (1993)). This has suggested that all slow movements are executed on a pulsatile basis. The idea of obligatory pulsatile control is actually quite old (Travis 1929, Tiffin and Westhafer, 1940)) but has recently been reworked (Bye and Neilsen, 2010; the BUMP theory). There are at least two difficulties with the idea of a central generator. First, how many such generators are there? One per motor unit, one per muscle, one per movement or one per person? Second, central generators operating at ~ 10 Hz during posture and movement have not been confidently identified.

The other half of the tremor story (the "mechano-reflex component") has also been studied. The "mechano" part is the resonant properties of the limbs. It may be augmented by appropriately phased "reflex" activity (Lippold, 1970). Resonance results from the interaction of the stiffness of the muscles and the inertia of the moving parts of the limb. In recent work, we have shown that the complete spectrum of tremor can be economically explained by resonance. A simple way to demonstrate this is to see if a specific form of EMG is necessary to generate tremor, or whether a realistic tremor can be created by an entirely random neural input. In one approach we compared real tremor to that produced by a simple resonant model. The resonant model recreated the tremor spectrum when driven by real EMG or by an entirely random artificial input. We concluded that the contribution of any central component must therefore be minimal (Lakie et al 2012). In the second approach we drove relaxed limbs with random artificial excitation and again showed that a realistic tremor resulted.

One of the key planks of the division of tremor into central and mechano-reflex components was that they occupied distinct and identifiable parts of the frequency spectrum. For some time, however, it has been known that the resonant frequency of a limb cannot be described by a single value. Skeletal muscles are thixotropic so that they decrease their stiffness with movement (Lakie et al 1984). We have shown that this feature can also be captured very well by a simple resonant model. Fig 1 shows hand tremor acceleration spectra recorded from a postural (static) and slowly moving (dynamic) limb. During movement the tremor size greatly increases (by approximately an order of magnitude) and decreases in frequency. This behaviour is also recreated by our simple resonant model using appropriately sized random inputs or recorded EMG.

For finger tremor the resonant frequency is thought to be higher than the wrist – usually greater that 20 Hz. Recent work leads us to question this assumption, because the frequency of finger resonance will reduce very considerably with movement. The tremor spectrum with its two peaks is usually thought to represent coexisting and distinguishable central and mechano-reflex mechanisms. We alternatively suggest that the two peaks may both represent resonance. The high frequency peak occurs when the finger is stationary and the muscles are stiff and the lower frequency occurs during movement when the muscle stiffness is much decreased.

We suggest that the finger tremor frequency is related to the speed of movement. When quasi-stationary, (postural), stiffness and resonant frequency are high and during movement both are reduced. Our conclusion is that as far as physiological tremor is concerned the role of a central component is negligible. Peripheral factors are extremely important and mechanical resonance is fundamental. It is possible that the resonant properties are complemented by reflex activity. One caveat is that the situation for pathological tremor is clearly different. Central oscillators are clearly involved in the genesis of Parkinsonian tremor and at least some forms of essential tremor.

Pattern control of human locomotion

Y. Ivanenko

Laboratory of Neuromotor Physiology, Fondazione Santa Lucia, Rome, Italy

Interaction of central and peripheral factors in the control of human posture and locomotion is a long standing topic. As Sherrington so accurately expresses in the statement "posture follows movement like a shadow," this highlights the interrelation of posture and movement . Tonogenic circuitry is a component of several, diverse supraspinal structures, including rostral ward, for example, the reticular formation, vestibular nuclei, the cerebellum, and selected mesodiencephalic nuclei. Here the two aspects of the locomotor circuitry functioning will be discussed: importance of muscle tone and development of locomotion in humans. Any reflection on the nature of human bipedalism should include a consideration of the mechanisms determining the choice of unconscious habitual posture. Disturbances in postural tone may also result in the emergence of quadrupedal gait in humans. Human stepping movements emerge in utero and show several milestones during development to independent walking. We examined the development of the spinal motor output by identifying the basic patterns of lumbosacral motoneuron activity from multimuscle recordings and by mapping the distribution of motoneuron activity in the lumbosacral spinal cord in stepping newborns, toddlers, preschoolers and adults. Muscle activity during human locomotion is accounted for by a combination of few basic patterns, each one timed at a different phase of the gait cycle. In particular, the two basic patterns of stepping neonates are retained through development, augmented by two new patterns first revealed in toddlers. The alternating spinal motor output is consistent with a simpler organization of neuronal networks in neonates. The development of human locomotion from the neonate to the adult starts from a rostrocaudal excitability gradient and involves a gradual functional reorganization of the pattern generation circuitry.

Pulmonary vascular mechanics: Important contributors to increased right ventricular afterload of pulmonary hypertension

Z. Wang and N.C. Chesler

Biomedical Engineering, University of Wisconsin, Madison, WI, USA

Chronic hypoxia causes pulmonary vasoconstriction and vascular remodeling, which lead to hypoxic pulmonary hypertension (HPH). HPH is associated with living at high altitudes and is a complication of many lung diseases, including chronic obstructive pulmonary disease, cystic fibrosis, and obstructive sleep apnea. Pulmonary vascular changes that occur with HPH include stiffening and narrowing of the pulmonary arteries that appear to involve all vascular cell types and sub-layers of the arterial wall. Right ventricular (RV) changes that occur with HPH include RV hypertrophy and RV fibrosis, often with preserved systolic and diastolic function and ventricular-vascular coupling efficiency. Both vascular stiffening and narrowing are important contributors to RV afterload via increases in oscillatory and steady ventricular work, respectively. The increased blood viscosity that occurs in HPH can be quite dramatic and is another important contributor to RV afterload. However, the viscosity, vascular mechanics and ventricular changes that occur with HPH are all reversible. Furthermore, even with continued hypoxia vascular remodeling does not progress to the obliterative, plexiform lesions that are seen clinically in severe pulmonary hypertension. In animal models, the RV changes appear adaptive, not maladaptive. In summary, HPH-induced vascular mechanical changes affect ventricular function but both are adaptive and reversible, which differentiates HPH from severe pulmonary hypertension. The mechanisms of adaptation and reversibility may provide useful insight into therapeutic targets for the clinical disease state.

The TGFbeta-BMP signalling pathway in pulmonary vascular homeostasis and disease

P.D. Upton, L. Long, A. Crosby, R.J. Davies, X. Yang, T. Tajsic, M. Southwood and N.W. Morrell

Medicine, University of Cambridge, Cambridge, UK

Germ-line mutations in the bone morphogenetic protein type II receptor (BMPR-II) gene cause the majority of heritable pulmonary arterial hypertension (PAH) cases. PAH is a subset of the spectrum of pulmonary hypertension (PH) disorders, including hypoxia-related lung diseases.

BMPR-II belongs to the Transforming Growth Factor beta (TGFβ) receptor superfamily. Bone morphogenetic proteins (BMPs), via BMPR-II, activate the canonical Smad1/5/9 pathway to induce target genes, such as ID1-4. TGFβs (TGFβ1-3), signalling via the ALK5 receptor, regulate various cellular processes through the canonical Smad2/3 pathway. Dysregulated TGFβ1 signalling is pathogenic in fibrotic kidney and lung diseases. Our studies have addressed whether BMPR-II loss is a common feature of PH and if it correlates to enhanced TGFβ1 signalling in PH. This question has been addressed via studies of interaction between the BMP and TGFβ pathways in animal PH models and human pulmonary artery smooth muscle cells (PASMCs).

PH can be induced in rats by injecting the plant alkaloid, monocrotaline, resulting in progressive disease (MCT-PAH), or exposure to chronic normobaric hypoxia (FiO2 10% O2). In our studies, both hypoxic PH and MCT-PAH were associated with reduced lung BMPR-II protein and mRNA (1). However, significant increases in TGFβ1 and decreased Smad/ID responses were only observed in MCT-PAH(1). To investigate the role of TGFβ1 further, we administered a pharmacological inhibitor of the TGFβ type I receptor, ALK5. This inhibitor prevented disease progression in the MCT-PAH model, but not in hypoxia (1).

In vitro studies have also been performed using PASMCs from donor lungs and BMPR-II mutation positive PAH PASMCs. The mutation-bearing PASMCs exhibit reduced BMP4 responsiveness(2). TGFβ1 attenuated BMP4-mediated ID1/2 induction and activation of a Smad-dependent luciferase reporter, yet did not alter Smad phosphorylation. Conversely, BMP4 did not

alter TGFβ1-mediated responses. The inhibitory effect of TGFβ1 upon BMP4 responses was reversed by ALK5 inhibition and by Smad3 siRNA, but was unaffected by Smad2 siRNA.
In conclusion, our studies have shown that BMPR-II loss is common to the hypoxic and MCT PH models, but systemic ALK5 inhibition is only effective in the MCT model, highlighting a specific role for TGFβ1 in vascular remodelling in MCT-PAH. On the background of reduced BMPR-II, TGFβ1 exerts a potential pathogenic role via inhibition of the BMP-Smad transcriptional pathway through a Smad3-dependent mechanism. Therefore, intravenous anti-TGFβ1 therapy may be more effective in PAH, particularly related to BMPR-II mutations, rather than hypoxic PH.

Pulmonary hypertension and the right ventricle in hypoxia

R. Naeije

Erasme University Hospital, Brussels, Belgium

Hypoxia causes pulmonary vasoconstriction. Regional hypoxic vasoconstriction improves the matching of perfusion to alveolar ventilation. Global hypoxic vasoconstriction increases right ventricular afterload. The hypoxic pulmonary pressor response is universal in mammals and in birds, but with considerable inter-species and inter-individual variability. Chronic hypoxia induces pulmonary hypertension in proportion to initial vasoconstriction. Chronic hypoxia also is associated with an increase in red blood cell mass, which aggravates pulmonary hypertension by an increased blood viscosity. Hypoxic vasoconstriction is a quasi-immediate response followed by vascular remodeling after a as soon as after 6-8 hours to become largely irreversible with supplemental oxygen after 24 to 48 hours of hypoxic exposure. Hypoxic pulmonary hypertension in humans is usually mild to moderate, but pulmonary vascular pressure-flow relationships are steep, which corresponds to a substantial afterload on the right ventricle during exercise. This limits aerobic exercise capacity be a decrease in maximum right ventricular flow output. A partial recovery of maximum oxygen uptake has been reported with intake specific pulmonary vasodilating interventions in hypoxic subjects. While there are very few reported measurements of cardiac function during exercise, resting echocardiographic examinations disclose subtle deteriorations in both systolic and diastolic function, with right ventricular predominance. These findings are more pronounced in patients with chronic mountain sickness, but their clinical significance remains incompletely understood.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA80

Systems medicine of neurogenic hypertension

J. Schwaber

Thomas Jefferson University, Philadelphia, PA, USA

High-throughput data are extremely variable. The variability is such that it does not appear to represent deviation around a mean, with samples drawn from a single distribution - it appears more consistent with multiple distinct subtypes or states within the population. “Precision medicine” requires we treat this variability and complexity “not as a glitch but as a feature”. In this regard we view the genome, and thus cell phenotype, as highly adaptive, dynamic in response to changing environment. Our approach is to use the transcriptome, defined as RNA and RNA regulatory proteins, as a surrogate for phenotype, and to both analyze and drive the variability in neuronal phenotype. We take the transcriptome as a summary record of the unique experience of the organism, and indeed of each cell, over its history in the environment – and as not an end state but as highly malleable, including responses leading to disease. Thus, our goal is to develop a molecular physiology that incorporates variability.
We study the neural regulation of visceral homeostasis and take regional, pooled cell, and single cell samples in the central neural control system involved. We assay these neural samples at rest and in response to elevated blood pressure. Analysis of the resulting high-dimensional dataset reveals a remarkable complexity and heterogeneity of the samples and of their response to changes in blood pressure. These results demonstrate differential expression modules for each anatomically distinct neuronal group and neuronal type. We have been able to analyze the variability in a way that connects it to higher-level neurophysiological and neuroanatomical features of the system. The results suggest a novel concept of neuronal regulation of cardiovascular homeostasis arising from variability in the molecular physiology.
Our view is this approach may now enable a mechanistic molecular physiology of neural function and disease, involving constrained gene regulatory network models and multiscale models. Our multiscale models include the several cell types comprising brain tissue as they interact in innate neuroimmune inflammatory responses during the development of hypertension. We are developing the approach with the aim of discovering the adaptive responses involved in the development of neurogenic hypertension, thought to underlie the vast majority of all hypertension.

Peptide modulation of cardiac autonomic transmission

N. Herring

Burdon Sanderson Cardiac Science Centre, Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK

Beta-blockers are known to improve mortality post myocardial infarction and in chronic congestive heart failure where sympathetic drive to the heart is high. However, the release of additional sympathetic co-transmitters can have deleteri-

ous consequences for cardiac parasympathetic neurotransmission even in the presence of these medications. Stimulation of the cardiac vagus reduces heart rate, lowers myocardial oxygen demand, improves coronary blood flow and independently raises ventricular fibrillation threshold. Methods used to assess vagus function in humans have demonstrated that higher nerve activity is a protective prognostic indicator in several cardiovascular disease states. This presentation will discuss recent data demonstrating a direct action of the sympathetic co-transmitters neuropeptide-Y and galanin on the ability of the vagus to release acetylcholine (1, 2), as well a strong correlation between plasma neuropeptide-Y levels and coronary microvascular function in patients with ST-elevation myocardial infarctions being treated by primary percutaneous coronary intervention (3). Targeting neuropeptide-Y receptors pharmacologically may therefore be a useful therapeutic strategy both acutely during myocardial infarction and also during chronic heart failure. Such medications would be expected to act synergistically with beta-blockers and implantable vagus nerve stimulators to improve patient outcome.

Novel insights into cardiac vagal ganglion transmission *in situ*

L.M. Salo[1], R.M. McAllen[2], J.F. Paton[1] and A.E. Pickering[1]

[1]School of Physiology & Pharmacology, Bristol Heart Institute, University of Bristol, Bristol, UK and [2]Florey Neuroscience Institutes, University of Melbourne, Melbourne, VIC, Australia

Vagal drive to the heart is a key determinant of resting heart rate and respiratory sinus arrhythmia. Cardiac vagal tone is an important indicator of cardiovascular health, and loss of cardiac vagal tone is a feature of many cardiovascular disorders, including hypertension and heart arrhythmias. The cardiac ganglia are an important site for regulation of vagal drive to the heart, where depression of transmission may translate to loss of vagal tone. Attenuated ganglionic transmission has been shown in models of heart failure (1) and hypertension (2).

As cardiac vagal postganglionic neurons (CVNs) are located in a ganglionic plexus on the surface of the beating heart, it has hitherto been difficult to investigate how CVNs process ongoing and reflex evoked vagal activity. We have extended the working heart-brainstem preparation (WHBP, 3) and developed a model whereby we can make stable, intracellular recordings from CVNs. To begin to address any deficit in cardiac ganglionic transmission in disease states we first characterised how CVNs respond to ongoing cardiac vagal tone and activation of a number of vagally-mediated cardiorespiratory reflexes in Wistar rats (4).

Male Wistar rats (P18-32, n=39) were anaesthetised with 5% Halothane (until decerebration) for surgical set up of the working heart-brainstem preparation. The atria were opened, stabilised and the cardiac vagal ganglia exposed. Intracellular recordings were made from CVNs with sharp microelectrodes (65-170MΩ, 0.5M KCl). CVNs were classified as tonic or phasic depending on whether they produced tonic firing or single spikes in response to depolarising current pulses (500ms, 0.3Hz, 1-10nA), respectively. CVN responses to activation of chemo- (50μl, 0.03% NaCN i.a.), baro- (+20-50mmHg perfusion pressure ramps), diving (100μl, ~10°C aCSF to the nose) and von Bezold-Jarisch (phenylbiguanide; PBG, 200μg i.a.) reflexes were assessed. Examples of phasic (n=6) and tonic (n=6) CVNs were filled with biocytin (4%), fixed in 4% formaldehyde and then incubated with Streptavidin conjugated to Alexa Fluor 594 (red) dye (1:1000, 12-24hr). The cells were then morphologically characterised using fluorescence microscopy.

Stable intracellular recordings were made from 61 cardiac vagal ganglion cells with preserved central connections. Cardiac ganglion cells with vagal synaptic inputs (spontaneous, n=21; or electrically evoked from the vagus, n=3) were identified as principal neurones and showed tonic firing responses to injected current pulses as described previously (5). Cells lacking vagal inputs (n=37, presumed interneurones) were quiescent but showed phasic firing responses to depolarising current pulses. In principal cells the ongoing action potentials and EPSPs exhibited respiratory modulation, with peak frequency in post-inspiration. Action potentials arose from unitary EPSPs and autocorrelation of those events showed that each ganglion cell received inputs from a single active preganglionic neurone. Peripheral and cardiac chemoreceptor, arterial baroreceptor and diving response activation all evoked high frequency synaptic barrages in these cells, as well as a concomitant bradycardia. Principal cells responded to activation of all reflexes indicating a convergence of reflex pathways. EPSP amplitudes showed frequency dependent depression, leading to more spike failures at shorter inter-event intervals. Marked temporal summation of EPSPs occurred only during activation of an intense von Bezold-Jarisch reflex response where EPSP frequency was so high (151Hz) that they summated to produce a depolarising envelope (+10mV). All imaged cells had identifiable processes, which were divided into three classes: monopolar (5/12), dipolar (4/12) and multipolar (3/12). Most cells had a long, recognisable axon (9/12), and none had extensive dendritic arrangements. Morphometrically, there was no significant difference between tonic and phasic cells as assessed by their mean soma area, length or diameter.

These data show that activation of vagally-mediated reflexes excite a common pool of vagal postganglionic neurones shared by numerous cardiorespiratory reflexes, with no evidence of recruitment of ganglionic interneurons during reflex activation. There do not appear to be marked morphological differences between 'tonic' (putative principal ganglion neurones) or 'phasic' (putative interneurones) cells, despite markedly different synaptic and intrinsic electrophysiological properties. These findings indicate that rather than integrating convergent inputs, cardiac vagal postganglionic neurones can gate preganglionic inputs, so regulating the proportion of central

parasympathetic tone that is transmitted on to the heart. We plan to assess how this is altered in cardiovascular disease states.

SA83

Causes and benefits of respiratory sinus arrhythmia

A. Ben-Tal[1], S.S. Shamailov[1] and J.F. Paton[2]

[1]INMS, Massey University, Auckland, New Zealand and [2]School of Physiology & Pharmacology, University of Bristol, Bristol, UK

Respiratory sinus arrhythmia (RSA) is a phenomenon where heart-rate (HR) varies with respiration. It is widely accepted that the loss of RSA is a prognostic indicator for cardiovascular disease and that the prominent presence of RSA indicates a healthy cardiac system, yet the reasons for this are still being debated (Larsen et al. 2010). One controversy is over the main mechanism that gives rise to RSA. While most investigators agree that RSA is mainly due to direct central respiratory modulation of the parasympathetic cardiac signal, others argue that RSA is mediated by the baroreflex responding to blood pressure oscillations triggered by the abdominal thoracic pump (Eckberg 2009). Another controversy is over the physiological function of RSA. Hayano et al. (1996) hypothesized that the physiological function of RSA is to match ventilation and perfusion in the lungs and thus optimize oxygen (O2) uptake and carbon dioxide (CO2) removal. Recently, using mathematical models, we showed that RSA may serve to minimize the energy expenditure of the heart while keeping arterial CO2 levels at physiological tensions (Ben-Tal et al. 2012); our theoretical study did not support Hayano's hypothesis.

Our study was performed using different mathematical techniques and different models. First, the optimal HR was calculated using techniques from optimal control theory in a simplified model of gas exchange. We found that the calculated HR was remarkably similar to RSA and that this became more profound under slow and deep breathing. Second, the HR function was prescribed and the cardiac work, as well as the volumes of O2 and CO2 taken up or removed by the blood respectively were calculated in a more detailed model of gas exchange. We found that cardiac work was minimized for RSA-like HR functions when the blood partial pressure of CO2 was controlled, most profoundly under slow and deep breathing and that although gas exchange efficiency improved with slow and deep breathing and with increased mean heart rate, this was unrelated to RSA. Third, we tested the two hypotheses using a newly developed minimal model for the neural control of HR in which RSA appears naturally and found similar results. The newly developed minimal model for the neural control of HR assumes that the heart period is affected primarily by the parasympathetic signal, with the sympathetic signal taken as a constant. We included the baroreflex, mechanical stretch-receptor feedback from the lungs, and central modulation of the cardiac vagal tone by the respiratory drive, but we omitted the chemoreflex. Our model mimics a range of experimental observations and provides several new insights. Most notably, the model can mimic the growth in the amplitude of RSA with decreasing respiratory frequency which then decreases at frequencies below 7 breaths per minute (for humans) and predicts that the decrease in the amplitude of RSA at low breathing frequencies is due to the baroreflex (we show this both numerically and analytically with a linear baroreflex). Another new prediction of the model is that the gating of the baroreflex leads to the dependency of RSA on mean vagal tone. These findings provide new insights into potential reasons and benefits of RSA under physiological conditions.

Inhibitory synaptic plasticity of GABAergic synapses in the hippocampus

M. Woodin

University of Toronto, Toronto, ON, Canada

The hippocampus plays a central role in memory formation in the mammalian brain. Its ability to encode information is thought to depend on the plasticity of synaptic connections between neurons. Pyramidal neurons from the CA3 produce monosynaptic excitatory postsynaptic potentials (EPSPs) followed rapidly by feedforward (disynaptic) inhibitory postsynaptic potentials (IPSPs). Long-term potentiation (LTP) of glutamatergic EPSPs is the leading model of synaptic plasticity, in part due to its dependence on NMDA receptors (NMDARs), which are also required for spatial and temporal learning in intact animals. Using whole-cell recording in hippocampal slices from adult rats, we find that the efficacy of synaptic transmission from CA3 to CA1 can be enhanced without the induction of glutamatergic LTP. We show that the induction of GABAergic plasticity at feedforward inhibitory inputs results in the reduced shunting of excitatory currents, producing a long-term increase in the amplitude of Schaffer collateral-mediated postsynaptic potentials. This GABAergic plasticity weakens inhibition due to a depolarization of the reversal potential for GABAA receptor currents (EGABA) through a decrease in the function of the neuron-specific K+-Cl- cotransporter KCC2. This form of inhibitory synaptic plasticity is termed disinhibition-mediated long-term potentiation (LTP). We found that disinhibition-mediated LTP is not restricted to the paired pathway, but rather is expressed to the same extent at

unpaired control pathways. However, the overall strength of GABAergic transmission is maintained at the unpaired pathway by a heterosynaptic increase in GABAergic conductance. The pairing-induced depolarization of EGABA at the paired and unpaired pathways required Ca2+-influx through both the L-type voltage-gated Ca2+ channels and NMDA receptors. However, only Ca2+-influx through L-type channels was required for the increased conductance at the unpaired pathway. As a result of this increased GABAergic conductance, disinhibition-mediated LTP remains confined to the paired pathway and thus is synapse specific, suggesting it may be a novel mechanism for hippocampal-dependent learning and memory.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

GABAergic synaptic plasticity in the developing spinal cord

P. Wenner

Emory University, Atlanta, GA, USA

Homeostatic plasticity refers to the mechanisms that a cell or network are thought to employ, in order to homeostatically maintain a set level of spiking activity. Such a process would be critical for ensuring that networks do not become too active or inactive. Homeostatic plasticity is studied by perturbing activity levels and identifying mechanisms that could contribute to the restoration of the original activity levels. These mechanisms include compensatory changes in excitatory and inhibitory synaptic strength, as well as changes in intrinsic cellular excitability. For instance, when spiking activity was blocked for 2 days in cultured neural networks, glutamatergic synaptic strength increased and GABAergic synaptic strength decreased. Homeostatic plasticity is typically studied in vitro at a stage when GABA or glycine are inhibitory. I will discuss the expression of homeostatic plasticity in the living embryonic spinal cord at an early developmental stage when both glutamate and GABA are depolarizing and excitatory. When spiking activity is blocked for 2 days in the living embryo, compensatory increases in excitatory GABAergic and glutamatergic synaptic strength are observed. Interestingly, GABAergic synaptic strength is increased through dramatic increases in intracellular chloride, thereby enhancing the driving force for these chloride-mediated currents. We are currently working to understand how this occurs. Not only are the compensatory changes in GABAergic synaptic strength mediated by changes in chloride levels, but it appears that the chloride-mediated GABAergic currents are involved in triggering homeostatic plasticity. When GABAa receptors were blocked in the embryo for 2 days, increases in GABAergic and glutamatergic synaptic strength were observed, and were even larger than following activity blockade. GABAergic synaptic strength was again increased through chloride accumulation. We believe that activity blockade reduces the release of GABA, thereby reducing GABAa receptor activation, which then triggers changes in GABAergic and glutamatergic synaptic strength. This places the GABAa receptor, and possibly the depolarizing chloride current, as part of the sensing machinery that triggers homeostatic plasticity.

Alterations in KCC2 compromise GABAergic control of the HPA axis

J. Maguire

Neuroscience, Tufts University School of Medicine, Boston, MA, USA

Effective GABAergic inhibition requires the maintenance of the chloride gradient, which is primarily accomplished by the K+/Cl- co-transporter, KCC2, in the adult brain. Alterations in KCC2 expression and function have been demonstrated under pathological conditions and in specific cell types under physiological conditions, including following stress. The body's physiological response to stress is mediated by the hypothalamic-pituitary-adrenal (HPA) axis. Corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus (PVN) of the hypothalamus are at the apex of HPA axis control and these neurons are tightly regulated by robust GABAergic inhibition. In response to a stressful event, the inhibitory control over CRH neurons, arising from multiple brain regions and mediated by numerous receptor subtypes, must be very rapidly lifted. Here we demonstrate that following acute restraint stress in mice, there is a dephosphorylation of KCC2 residue Ser940, which regulates the surface expression and function of KCC2, and downregulation of total KCC2 expression in the PVN. In addition, we demonstrate excitatory actions of GABA following acute restraint stress on CRH neurons. Our data suggest that collapsing the chloride gradient, by dephosphorylation and downregulation of KCC2, alleviates the inhibitory GABAergic control of CRH neurons which is necessary to mount the physiological response to stress. In contrast, following acute restraint stress in mice, we do not observe alterations in KCC2 expression in the hippocampus. Interestingly, following chronic restraint stress, there is a dephosphorylation of KCC2 residue Ser940 and a downregulation of KCC2 in the hippocampus, associated with a shift in EGABA and increased excitability of CA1 pyramidal neurons. These alterations in KCC2 expression may play a role in mediating the known increased neuronal excitability in the hippocampus following chronic stress. These data demonstrate rapid changes in KCC2 function and dynamic changes in GABAergic inhibition in a brain region-specific manner following both acute and chronic stress. Furthermore, alterations in KCC2 may have implications for stress-related disorders, including epilepsy and depression.

The authors would like to thank Dr. Steve Moss for the generous gift of the phospho-specific KCC2 Ser940 antibody.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Ionic plasticity of GABAergic synapses by rapid regulation of the K-Cl cotransporter KCC2

P. Blaesse

Laboratory of Neurobiology, University of Helsinki, Helsinki, Finland and Institute of Physiology I, University of Münster, Münster, Germany

Cation-chloride cotransporters exert a major influence on the neuronal intracellular chloride concentration. Thereby, they are crucial for the Cl-dependent signalling mediated by $GABA_A$ and glycine receptors. Short-term and long-term changes in $[Cl^-]_i$ based on changes in the activity of the chloride transporters lead to ionic plasticity, i.e. quantitative and qualitative changes in the action of GABA and glycine. Such changes in inhibitory signalling occur during development, when a shift from relatively high intracellular Cl^- levels towards lower levels is seen in most central neurons. In addition, such changes may also contribute to pathological neuronal activity, e.g., epilepsy (Kahle et al., 2008; Blaesse et al., 2009).

KCC2, a K-Cl cotransporter, is the main Cl^- extruder in central neurons and responsible for an inwardly-directed Cl^- electrochemical gradient that is required for classical hyperpolarizing GABAergic inhibition. Numerous studies have shown that posttranslational modifications play a pivotal role in the short-term regulation of the transporter under physiological and pathophysiological conditions.

Mimicking certain aspects of human epilepsy in animal models and in vitro revealed new molecular mechanisms involved in the fast regulation of KCC2. In contrast to the known down-regulation of KCC2 by increased neuronal activity in mature neurons, a single seizure episode led to a rapid activation of KCC2 in the neonatal rat hippocampus, when KCC2 is not yet active under control conditions (Khirug, Ahmad et al., 2010). The activity-dependent functional up-regulation of KCC2 in immature neurons was paralleled by an increase in KCC2 surface expression. Signalling via the TrkB tyrosine kinase was essential for the activity-induced changes in KCC2-mediated Cl^- transport and KCC2 trafficking. Interestingly, TrkB signalling is also crucial for the activity-dependent down-regulation of KCC2 in the more mature system, pointing to a developmental sign change within the TrkB-KCC2 signalling cascade.

In addition to changes in trafficking, activity-dependent cleavage of KCC2 by the plasticity-associated protease calpain has been identified as a new mechanism for the fast functional down-regulation of KCC2 (Puskarjov, Ahmad et al., 2012). The application of the glutamate receptor agonist NMDA or the induction of interictal-like activity led to a fast reduction of KCC2 protein level and of KCC2-mediated Cl^- transport in hippocampal CA1 neurons. Both effects were blocked by inhibitors of the calcium-activated protease calpain.

The role of the different mechanisms and of the resulting ionic plasticity of GABAergic signalling under physiological (e.g., in learning-associated synaptic plasticity) and pathological conditions will be discussed.

Hydrogen sulfide in the vascular system: an overview of its roles and mechanisms

R. Wang

Lakehead University, Thunder Bay, ON, Canada

"Hydrogen sulfide, a lethal gas best known for smelling like rotten eggs, turns out to play key roles in the body – a finding that could lead to new treatment for heart attack victims and others" (Scientific American, 302: 66-71, 2010). Research over the last decade has revealed critical biomedical implications of hydrogen sulfide (H2S), a gasotransmitter produced in almost every type of cells with cysteine and homocysteine as substrates. Cystathionine gamma lyase (CSE) plays the most important role in cardiovascular system for the endogenous production of H2S. It is localized in the cytosol of vascular smooth muscle cells (SMCs) under resting conditions. H2S produced in the cytosol of SMCs stimulates KATP channels, leading to vascular relaxation. CSE can be transported into mitochondrion upon the sustained elevation of intracellular calcium level to produces H2S inside mitochondria. The mitochondria-produced H2S decreases ATP production under nomoxia condition but increases it under hypoxia condition. This oxygen-sensitive mitochondrial production of H2S may be important for regulation of vascular remodeling and proliferation. On the other hand, H2S is produced in vascular endothelial cells (ECs) via a calcium/calmodulin-dependent mechanism. Deficiency in endothelium production of H2S leads to delayed wound healing, suppressed endothelial proliferation and migration, vulnerability of endothelium to hyperglycemia damage, abolished endothelium-dependent vasorelaxation, and age-dependent development of hypertension. Micro-electrode recording of the membrane potential changes in endothelium-intact peripheral vascular tissues has provided direct evidence that H2S is an endothelium-derived hyperpolarizing factor (EDHF). As an EDHF, H2S induces greater hyperpolarization of SMCs from female mouse mesenteric arteries than that from male ones. In conclusion, the production of hydrogen sulfide in cardiovascular system is mediated by different mechanisms in different types of cells. By regulating mitochondrial functions and by acting on KATP channels in vascular SMCs and small to medium conductance KCa channels in ECs (as an EDHF), H2S differentially modulates the proliferation of SMCs and ECs and induces vasorelaxation.

SA90

Role of H2S balancing oxidative stress and antioxidant pathways and modulating vascular tone

D. Henrion

Vascular Biology, INSERM -CNRS, Angers, France

The microcirculation is sensitive to small changes in pO2 and pCO2 as well as to gasotransmitter such as nitric oxide (NO) and carbon monoxide generated by the vascular endothelium [1, 2]. Resistance arteries, located upstream the microvasculature control local blood flow in part through their myogenic reactivity [3], Hydrogen sulfide (H2S), is a potent environmental toxic gas, which has recently been described as a gasotransmitter, similar to nitric oxide or carbon monoxide. Endogenous synthesis of H2S has been documented in both physiological and pathological conditions. In the vasculature, H2S is synthesized from cysteine by cystathionine-γ-lyase in smooth muscle cells and 3-mercaptopyruvate sulfuresterase and cystathionine-γ-lyase in the endothelial cells [4]. Depending on the pathophysiological condtions, H2S has been reported to exhibit pro- and anti-inflammatory properties. H2S has been shown to induce contraction at low doses through the inhibition of the conversion of citrulline into arginine by eNOS and relaxation at high doses through by activation of K+ATP channels in the rat and mouse aorta. More recent investigations have shown that H2S induces a "suspended animation-like" state leading to a better protection of animals against lethal hypoxia. Similarly, the pre-treatment of rats with H2S (intravenous injection or inhalation) prevents death after controlled but unresuscitated hemorrhage.
Recent studies have shown that NaHS is protective against the effects of ischemia reperfusion induced by controlled hemorrhage in rats. NaHS was also able to improve cardiovascular homeostasis in the early resuscitation phase after hemorrhagic shock, most probably through a reduction of oxidative stress [5]. Consequently, the use of NaHS represents a promising therapeutic perspective in limiting the consequences of ischemia reperfusion. The role of H2S in the balance between pro- and antioxidant mechanisms in the vasculature will be detailed.

Homocysteine to hydrogen sulfide: *in vitro*, *ex vivo* and *in vivo*

S.C. Tyagi

University of Louisville, Louisville, KY, USA

Hydrogen sulfide (H(2)S) is identified as a regulator of various physiological events, including the hypertension, H(2)S is produced as a metabolite of homocysteine (Hcy) by cystathionine β-synthase (CBS), cystathionine γ-lyase (CSE), and 3-mercaptopyruvate sulfurtransferase (3MST). Although Hcy is recognized as vascular risk factor at an elevated level [hyperhomocysteinemia (HHcy)] and contributes to vascular injury leading to hypertension, the exact mechanism was unclear. To determine whether conversion of Hcy to H(2)S mitigates hypertension. Ex vivo renal artery culture with CBS, CSE, and 3MST triple gene therapy generated more H(2)S in the presence of Hcy, and these arteries were more responsive to endothelial-dependent vasodilation compared with nontransfected arteries treated with high Hcy. Cross section of triple gene-delivered renal arteries immunostaining suggested increased expression of CD31 and VEGF and diminished expression of the antiangiogenic factor endostatin. In vitro endothelial cell culture demonstrated increased mitophagy during high levels of Hcy and was mitigated by triple gene delivery. Upregulated matrix metalloproteinases-13 and downregulated tissue inhibitor of metalloproteinase-1 in HHcy were normalized by overexpression of triple genes. Together, these results suggest that H(2)S plays a key role in hypertension during HHcy.

Transient receptor potential ankyrin 1 receptors mediate hydrogen-sulphide-induced calcitonin-gene-related-peptide release and cutaneous vasodilatation

Z. Hajna, G. Pozsgai, T. Bagoly, M. Boros, . Kemény, Z. Helyes, J. Szolcsányi and E. Pintér

Department of Pharmacology and Pharmacotherapy, University of Pécs, Faculty of Medicine, Pécs, Hungary

Introduction: Capsaicin-sensitive sensory neurons express Transient Receptor Potential Ankyrin 1 (TRPA1) and Vanilloid 1 (TRPV1) receptors. TRPA1 can be activated by several chemical stimuli, such as allylisothiocyanate (AITC), the pungent agent of mustard oil, resulting in the release of vasoactive inflammatory neuropeptides like calcitonin-gene-related-peptide (CGRP). The gaseous mediator hydrogen-sulphide (H2S) has been recently suggested to act on capsaicin-sensitive sensory neurons. Therefore, the aim of our present study was to investigate the involvement of TRPA1 receptors in H2S-evoked CGRP-release from sensory nerves in vitro and microcirculatory changes in vivo.
Methods: In vitro experiments were performed on isolated tracheae of male and female Wistar rats (200–250 g). Tracheae were removed in deep anaesthesia (sodium thiopentone, 100 mg/kg, i.p.). Sensory nerve terminals of the isolated rat tracheae were stimulated by increasing concentrations of AITC or the H2S-donor NaHS and CGRP-release was measured by radioimmunoassay. The effects of the TRPA1 antagonist HC-

030031 and the TRPV1 antagonist BCTC were tested on this response.
In vivo experiments were carried out on Balb/c mice for testing pharmacological inhibition by HC-030031, while TRPA1 (TRPA1-/-) and TRPV1 gene-deficient (TRPV1-/-) mice were compared to their wild types (WTs, 25-30 g). Measurements were performed under ketamine (100 mg/kg, s.c.) and xylazine (5 mg/kg, s.c.) anaesthesia. Vasodilatation of the murine ear was evoked by AITC (15 μl, 2%) or NaHS (15 μl, 5%) and skin blood flow was measured by laser Doppler imaging for 30 minutes in case of AITC-, and for 50 minutes in case of NaHS-application.
Results: Both AITC and NaHS elicited concentration-dependent release of CGRP in the rat tracheae. CGRP-release induced by AITC amounted to 1.46±0.31 fmol/mg, which was only 0.14±0.06 fmol/mg in the presence of 100 μmol/l of HC-030031. NaHS-evoked CGRP-release reached 0.47±0.09 fmol/mg, which was only 0.0008 fmol/mg when HC-030031 (100 μmol/l) was applied. In the presence of BCTC, NaHS-induced CGRP-release amounted to 0.52±0.05 fmol/mg.
AITC evoked an increased skin blood flow with a maximum value of 27.87%±2.31% above baseline at 6 minutes. 30 or 100 mg/kg of HC-030031 inhibited AITC-evoked vasodilation by 54.5% and 53.6%, respectively. NaHS increased cutaneous microcirculation with a peak value of 67.42%±4.87% above baseline at 48 min. 30 and 100 mg/kg of HC-030031 inhibited NaHS-induced vasodilatation by 24.6% and 51.4%, respectively.
In wild type mice, maximum value of blood flow amounted to 17.36%±4.1%. In the TRPA1-/- animals it reached only -1.69%±4.17%, while in the TRPV1 knockouts it peaked at 17.77%±5.28%. In WTs, NaHS caused a 44.18%±3.19% increase of microcirculation. In the TRPA1-/- mice it reached only 23.75%±4.09%, while in the TRPV1-/- animals it peaked at 35.73%±3.29%.
Conclusion: Similarly to the effect of AITC, NaHS also evoked a concentration-dependent CGRP-release, which was inhibited by HC-030031, but not by BCTC. Likewise AITC, NaHS also increased cutaneous microcirculation in the mouse ears, and this vasodilatory response to NaHS could be ameliorated by HC-030031. Blood flow of TRPA1-/-, but not the TRPV1-/- mice showed significantly smaller increase in response to NaHS compared to the wild types.
Activation of TRPA1 receptors plays an important role in H2S-induced CGRP-release and cutaneous vasodilatation in the murine ear, while TRPV1 receptors are not involved in these processes. Our results highlight that TRPA1 receptor activation should be minded as a potential mechanism of vasoactive effects of H2S.

Mitochondria-targeted slow release hydrogen sulfide donors: a novel link to an old 'tail'?

M. Whiteman

University of Exeter Medical School, Exeter, UK

Hydrogen sulfide (H2S) has recently been identified as an endogenous redox active gaseous mediator and proposed as an endogenous regulator of nitric oxide (NO) bioavailability, vascular tone and inflammation. Novel slow release H2S donor (SRHD) molecules such as GYY4137 [1,2] have been shown to regulate blood pressure in experimental and genetically induced hypertension and to inhibit tissue damage, oedema, cell death and inflammatory signalling [3-5] in sepsis and arthritis [6]; conditions well known to involve perturbed mitochondrial function and oxidative stress. In this study we have synthesised a series of compounds containing a mitochondria-targeting moiety (triphenylphosphonium), a C2-C18 'linker' and H2S releasing moieties containing either a dithiolethione or thiohydroxybenzamide 'tail' (mitochondria-targeted SRHDs; mtSRHDs).
To investigate H2S-mediated cytoprotection in vitro, we exposed human microvascular endothelial cells (HMEC) to oxidative injury with H2O2, 4-hydroxynonenal (4-HNE) and SIN-1 (or a cocktail of oxidants) in the presence or absence of either mitochondria-targeted H2S donors (< 100nM) or non-targeted SRHDs (GYY4137, AP67, AP72; < 200μM) for comparison. Oxidant induced cellular toxicity was assessed using standard metabolic assays, mitochondrial membrane depolarisation assays, ATP content, phosphatidylserine externalisation, caspase activation and activity etc. Intracellular oxidant production was estimated using intracellular fluorescent probes, DCF-DA, mitosoxRed and dihydroethidium. We also determined the effects on of SRHDs/mtSRHDs systemic blood pressure, heart and breathing rates in spontaneously hypertensive and L-NAME-treated rats.
Preliminary experiments showed a C10 linker to optimal and AP39 (dithiolethione) and AP123 (hydroxythiobenzamide) were chosen for further study. Treatment of HMEC with SIN-1, H2O2 (100μM) 4-HNE (10μM) for 18h resulted in significant cytotoxicity (ANOVA,$p<0.01$). The toxicity of individual oxidants or oxidants used in combination to achieve similar effects (e.g. 50μM SIN-1/H2O2 with 2μM 4-HNE) was significantly inhibited by non-targeted SRHDs (100μM; $p>0.01$ all treatments). However, in each cytotoxicity assay the potency was substantially increased by targeting H2S delivery to mitochondria (AP39/123, 100nM; $p<0.01$). In spontaneously hypertensive and L-NAME (30mg/kg) treated rats, AP39 (1μM/kg) induced a rapid and sustained decrease in blood pressure and heart rate; an effect more pronounced than non-targeted SRHDs AP67 (30μM/kg) or GYY4137 (133μM/kg) [1].
These data suggest SRHDs can inhibit and / or reverse oxidative stress-mediated vascular cell injury and regulate vascular tone. Furthermore, strategies which increase H2S bioavailability, and in particular target mitochondria, represent a new therapeutic opportunity to limit mitochondrial and endothelial dysfunction.

JAM'S in inflammation and vascular disease

B. Imhof

dept pathology and Immunology, CMU / university geneva, Genève 4, Switzerland

We investigate the roles of junctional adhesion molecules (JAMs) in pathology of leukocyte migration, inflammatory diseases and angiogenesis. Simultaneously with other laboratories we discovered the vascular adhesion molecules JAM-B and JAM-C. Expression and production of recombinant JAMs enabled the development of a large panel and monoclonal and polyclonal antibodies, and we produced transgenic mice overexpressing JAM-C in the vasculature and JAM-C and JAM-B deficient mice. Using these reagents and the gene modified animals we showed JAM-C involved in immune responses against microorganisms preventing pneumonia and studied the role of this moleculkes in immunity against Leishmaniasis . Furthermore, antibodies against JAM-C reduced the severity of acute and chronic inflammatory pathologies such as pancreatitis, peritonitis, rheumatoid arthritis. These effects of JAM-C seem to be due to its role in leukocyte transendotheial migration. The molecules form a vascular barrier for tissue leukocytes returning back to the blood i.e. it contributes to the one-way traffic observed during leukocyte homing. In collaboration with Sussan Nourshargh, London we visualized neutrophils and monocytes reverse, polarised transendothelial migration. These events were detected by blocking JAM-C in vitro and in vivo using 3D intravital microscopy of inflammation following ischemia/reperfusion injury.
(JAM-C) is expressed by vascular endothelium and also by human but not mouse B lymphocytes. Together with Thomas Matthes, Geneva we recently described that the level of JAM-C expression defines B cell differentiation stages and allows the classification of marginal zone (JAM-C positive) and germinal center (JAM-C negative) B cell lymphomas. Now we found a role for this lymphocyte JAM-C in migration of human B cells, using a xenogeneic NOD/SCID human/mouse model. Treatment with anti-JAM-C antibodies reduced homing of normal and malignant human, JAM-C expressing B cells to bone marrow, lymph nodes and spleen. Blocking spleen homing is remarkable as most other anti-adhesion antibodies reduced homing of B cells only to bone marrow and lymph nodes but not to spleen. Plasmon resonance studies identified JAM-B as the major vascular ligand for JAM-C while homotypic JAM-C interactions remained at background levels. Accordingly, anti-JAM-C antibodies blocked adhesion of JAM-C expressing B cells to blood vessels in human and mouse lymphoid organs. In particular, JAM-B is highly expressed by the spleen vasculature.
We will review our work on JAM-C and JAM-B and compare it to the roles of JAM-A, the first molecule discovered and belonging to the JAM family.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Monocyte influx supports the proliferation of angiogenic microvessels under ischemic and inflammatory conditions

A. Woodfin, B. Ma and S. Nourshargh

William Harvey Research Institute, Barts and The London School of Medicine, Queen Mary University of London, London, UK

Angiogenesis is a common feature of chronic inflammatory and ischemic conditions, and is both driven by, and contributory to, the eventual pathological outcomes. An example of this can be seen in the development of atherosclerotic plaques, where neovascularisation facilitates monocyte infiltration into lesions, a process that contributes to plaque instability and eventual rupture, leading to thrombosis and vascular occlusion. Yet despite the tremendous interest in the role of angiogenesis in these disorders surprisingly little is known about the profile, dynamics and mechanisms of inflammation within angiogenic tissues. A major limiting factor here has been the lack of availability of suitable in vivo models for direct investigations of inflammatory events in angiogenic vessels.
We have developed a model of ischemic angiogenesis in the mouse cremaster, which is amenable to in vivo confocal imaging with high temporal and spatial resolution. This imaging system has been employed to characterise the angiogenic profile of this model and to investigate the link between immune cell infiltration and new vessel growth. At one week post induction of chronic ischemia, tissues exhibit a high density of small diameter, PECAM-1 expressing microvessels, with a functional lumen but a characteristically disordered morphology. A significant tissue infiltration of CX3CR1-eGFP+ cells of a monocytic lineage were noted at this time point, often forming close associations with angiogenic vessels.
Further analysis of the time course of infiltration and phenotype of these CX3CR1-eGFP+ cells has revealed that a large influx of GR1high/F4/80low M1 type monocytes is seen within one day of induction of ischemia. Subsequently these cells migrate within the tissue and undergo morphological and phenotypic changes, adopting a GR1low/F4/80high M2 like macrophage phenotype by one week post ischemia. Depletion of blood monocytes prior to induction of ischemia significantly inhibits the angiogenic response, demonstrating a role for these cells in vasculogenesis.

The present study into the relationship between myeloid cells and the induction and maintenance of chronic inflammation and angiogenesis aims to identify potential opportunities for therapeutic interventions in the context of chronic inflammatory and ischemic disorders.

Role of cholesterol in determining macrophage phenotype

T.J. Van Berkel, J. Kuiper and M. Van Eck

LACDR - Biopharmaceutics, Leiden University, Leiden, Netherlands

High plasma lipid levels form a prerequisite for the development of atherosclerosis. The recruitment of monocytes to the arterial wall is initiated by the local environment which must be modulated by lipidomic factors. Once monocytes in the arterial wall are converted to macrophages, deposition of excessive amounts of cholesteryl esters, leading to foam cell formation can be considered as a key event in the progression of atherogenesis. Macrophage cholesterol homeostasis involves a delicate balance between lipid influx and lipid efflux. Macrophages are incapable of limiting the uptake of lipids via scavenger receptors and therefore largely depend on cholesterol efflux pathways to maintain cellular lipid homeostasis. Important mediators of macrophage cholesterol efflux are ABCA1, which mediates the efflux of cholesterol to lipid-poor apo A-I. Furthermore ABCG1 and SR-BI can efflux cholesterol to mature HDL. As a consequence of compensatory mechanisms, the single ABCA1, ABCG1 or SR-BI deficiency in macrophages only leads to moderate effects on cholesterol efflux and atherogenesis. Combined deletion of ABCA1 and ABCG1 leads to massive lipid accumulation and foam cell formation of tissue macrophages, while massive foam cell formation, atherosclerotic lesion development and inflammation is also observed by combined deletion of macrophage ABCA1 and SR-BI. The combined macrophage deletions of ABCA1, ABCG1 and/or SR-BI show the essential function of these cholesterol transporters in macrophage foam cell formation and atherosclerotic lesion development. An enhancement of sytemic inflammation markers does accompany the extend of foam cell formation and the interaction between lipid accumulation and the inflammatory status might form an important factor for the pathological events during atherogenesis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA97

Role of adaptive immunity in foam cell inflammatory phenotype

K. Ley

La Jolla Institute for Allergy & Immunology, La Jolla, CA, USA

Macrophage-derived foam cells are a defining feature of atherosclerotic lesions. Vulnerable plaques contain more foam cells and larger necrotic cores. However, when foam cells are generated in vitro (Cho,H. et al. Physiological Genomics 29:149-160, 2007) or in mice (Spann,N.J. et al., Cell. 151:138-152, 2012), their overall phenotype is anti-inflammatory, not pro-inflammatory. Yet, in atherosclerotic lesions foam cells show a pro-inflammatory phenotype, based on phenotyping by immunofluorescence and other methods. This apparent discrepancy suggests that an additional factor not present in reductionist systems drives foam cell inflammation. We propose that this additional factor are CD4 T cells that provide pro-inflammatory cytokines including IFN-γ, IL-17 and TNF-α. Multiphoton microscopy of Apoe-/- mouse aortas show that CD11cYFP antigen-presenting cells become rounded and less motile, consistent with conversion to foam cells. We show that adoptive transfer of antigen-experienced CD44hiCD62L- CD4 T cells induces production of IFN-γ, IL-17 and TNF-α. IFN-γ is very efficient at increasing uptake of oxidized low density lipoprotein (oxLDL) in macrophages in culture. Our experiments suggest that both antigen-experienced T cells and a suspected autoantigen are present in Apoe-/- mice. These data also suggest that modulating the autoimmune response might be effective in preventing or treating atherosclerosis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Recruitment of Ly6Chigh monocytes is required for the enhancement of anti-inflammatory (M2) macrophage phenotype *in vivo* in atherosclerosis regression in mice

E.A. Fisher, Y. Vengrenyuk, N. Girgis and P. Loke

Medicine/Cardiology, New York Univ. Sch. of Med., New York, NY, USA

Blocking the progression of atherosclerotic lesions and inducing their regression are important clinical goals. We've reported several mouse models of atherosclerosis regression in which an improvement of plasma lipoprotein profiles results in a rapid reduction lesion macrophage content. Another common feature was a dramatic phenotypic enrichment of plaque CD68+ cells (macrophages) in markers of the anti-inflammatory (M2) state. Here, we investigate the origin of M2 macrophages in regressing lesions by modifying our original aortic transplantation model to include recipients whose monocytes lack the major receptors responsible for their recruitment into tissues. Aortic arch segments containing an atherosclerotic lesion from an apoE-/- mouse were transplanted into CCR2-/-, CX3CR1-/-, or CCR5-/- mice, in addition to WT and apoE-/- controls. Macrophage marker CD68+ area quantification data showed that the lack of CCR2 or CX3CR1 in transplant recipients completely blocked regression despite the reversal of dyslipidemia, while CCR5 deficiency had no effect. Since inflammation-prone Ly6Chigh monocytes require both CCR2 and CX3CR1 receptors to enter atherosclerotic lesions, our results suggest that the recruitment of new Ly6Chigh inflammatory monocytes is required for regression. Furthermore, CCR2-/- and CX3CR1-/- recipients lacked M2 macrophages in atherosclerotic lesions, suggesting that the M2 macrophages in regressing lesions are derived from the recruitment of inflammation-prone Ly6Chigh monocytes. Finally, we tested whether the M2 enrichment in regression follows the classical Il/4-STAT6 signaling pathway by using STAT6-/- mice as transplant recipients. The lack of STAT6 not only prevented upregulation of M2 markers, but also resulted in impaired lesion regression. In conclusion, we showed that newly recruited Ly6Chigh monocytes give rise to the anti-inflammatory M2 macrophages under regression conditions in a STAT6-dependent manner, and that both the recruitment of new cells and a functioning STAT6 pathway are also required for atherosclerosis regression. The results argue against the possibility that M1 macrophages in progressing lesions repolarize to the M2 phenotype under regression conditions in vivo and support the notion that regression is not a rewinding of progression, but requires the participation of newly recruited inflammation-prone monocytes that in this context promote the resolution of inflammation.

In the aortic transplantation procedure, mice are administered ketamine and xylazine.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA99

What do we mean by competency-based education and how does it apply to professional curricula?

W.R. Galey

Science Education, Howard Hughes Medical Institut, Bethesda, MD, USA

Although there is general consensus across the medical education community that graduates should be competent in the sciences there is little agreement as to what is meant by "competency". Many nations are moving to "competency-based" or competency influenced education. This symposium will explore how "competency" is being interpreted and implemented in various educational venues around the world. One such venue is the United States.
In 2007 Howard Hughes Medical Institute (HHMI) the largest philanthropy in the United States dedicated to biomedical research and science education partnered with the Association of American Medical Colleges (AAMC) to convene a group dedicated to defining the core science that should be mastered by students by the time of their graduation from medical school. The committee was charged with not only establishing the graduating scientific abilities for physicians but also defining the science students should have mastered by the time they matriculate into medical school.
The committee composed of clinical, medical school basic science and premedical science teachers met over a period of 18 months. The report of the committee published in 2009 titled Scientific Foundations for future Physicians (SFFP) https://www.aamc.org/students/download/302644/data/hhmi.pdf 1) established competencies as the goal of medical science education, 2) defined eleven overarching principles for science in medical education and 3) set eight science competencies for graduating physicians and eight competencies that all students should have mastered on matriculation to medical school. For each competency, Learning Objectives and Examples were given to guide the establishment of expectations as to the appropriate depth and application at which the competencies should be accomplished by learners.
It was recognized by the SFFP Committee that the growing knowledge of the natural world, especially the biological sciences, precludes the mastery of all science knowledge. Hence some information while important in particular disciplines or certain realms of endeavor are less important to understanding human biology, pathophysiological processes and the treatment of disease and should not be required. Further, recognizing that certain important concepts are shared across the natural science disciplines, the committee suggested that integration of learning might be more efficient than the separated learning of a concept in multiple disciplines. Acknowledging the increasing need to understand and apply quantitative information to medical practice the SFFP committee emphasized a need for a greater mastery of mathematical concepts statistics and computational sciences.
The SFFP Report and the Report of the MR5 Committee which reviewed the content and structure of the Medical College Aptitude Test (MCAT) used by most US medical schools to evaluate the preparedness of students wishing to enter medical school have influenced the nature of the revised MCAT to be initiated in 2015 https://www.aamc.org/students/applying/mcat/mcat2015/.
These reports are stimulating US colleges and Universities to examine how competencies in the sciences might be more effectively learned. Furthermore many medical schools are reexamining their admission requirements, the structure of their curricula and the methods of instruction.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA100

Competency based education: a European perspective

C. Karatzaferi

PE & Sports Science, University of Thessaly, Trikala, Greece

Competency based education (CBE) focuses on students acquiring knowledge and skills, called competencies, required for a particular course/degree. Mature students seem to be particularly suited for CBE, as they enter a course of study with variable backgrounds of knowledge and skills, usually aiming for a professional qualification. However, CBE is gaining ground in undergraduate courses as well. In truth, CBE core elements (such as laboratory experience, skills, problem solving, team work, ethics, student research and enquiry) pre-existed the formulation of CBE in the modern era. Nowhere is this so true than the medical sciences field. Physiology always played a key role in the curricula of medical studies and of health allied professions. However CBE implementation is fragmented and varied in Europe. In Greece the importance of physiology for the acquisition of medical/health allied competencies has been recognized almost from the beginning of the University system. This talk will discuss the implementation of CBE in Greece and will draw comparisons with European-wide examples.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA101

Aligning competencies in undergraduate and professional programs

D.U. Silverthorn

Integrative Biology, University of Texas, Austin, TX, USA

The move to competency-based education in the United States is gaining momentum, but there are still many institutions, particularly at the undergraduate level, that are hesitant to move away from traditional courses. Recent changes proposed for the testing and admission process for American medical schools have now focused attention on the premedical curriculum and its rigid course requirements in biology, chemistry, physics, and mathematics. Some universities are beginning to explore the use of competency-based education to condense these course requirements, thereby creating space in the curriculum for more behavioral science and liberal arts classes.
In 2009 the Association of American Medical Colleges partnered with the Howard Hughes Medical Institute (HHMI) and issued a report, Scientific Foundations for Future Physicians (SFFP, available at www.hhmi.org/grants/pdf/08-209_AAMC-

HHMI_report.pdf). The SFFP report called for the substitution of competencies in place of rigid course requirements for admission to medical school, and it described eight broad competencies that were fundamental background for beginning specialized medical education. Some of the intent of the SFFP report was to open the door for development of creative interdisciplinary curricula and for collaboration between disciplines. To support this objective, HHMI created the NEXUS project (www.hhmi.org/grants/office/nexus). For example, as part of NEXUS, an interdisciplinary team from the University of Maryland developed a physics course for life science students that emphasizes basic scientific competencies and uses biological examples to teach physical principles.
In the medical and academic institutions of the University of Texas System, a pilot project called Transformation in Medical Education (TIME) aims to shorten the time between high school and completion of the medical degree by using competencies to eliminate redundancies in the undergraduate and medical curricula. To accomplish this, we first created sets of competencies from those required for physician graduates. Now we are mapping competencies onto existing courses and using the map looking for opportunities to combine traditional courses, such as those in physics and physiology. This talk will show how this work has progressed and will discuss some of the obstacles to implementation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA102

The development of competency-based curriculum and quality assurance in Indonesian medical education

M. Irfannuddin Misbach

Physiology, University of Sriwijaya, Palembang, South Sumatra, Indonesia

The recent reformation of medical curriculum in Indonesia was stimulated by public concern about the quality of health care officers. The content-based curriculum produced graduates who were not able to follow advances in science and technology, and who lacked the technical and communication skills needed to effectively serve the community.
In 2006, the Indonesian Medical Council adopted seven categories of competencies as the main outcomes of the competency-based curriculum for physicians: communication, clinical skills, medical scientific foundation, health problem management, information management, self awareness, and professional ethics. The Council determined that rather than follow a core curriculum, Indonesian institutions must implement Ron Harden's SPICES curriculum design strategy.(1)
At the beginning, implementation of the reforms was slowed by resistance to student-centered and integration approaches, concerns that a problem based learning approach was incompatible with Asian culture, and gaps in institutional capability. The changes accelerated after the government involved professional medical associations and obtained support from foreign grants. However, faculty members still had difficulty matching new competencies to existing learning objectives and learning strategies, particularly for generic competencies.
As part of the reform, the Council implemented a national board examination and applied a quality assurance system to ensure graduates were able to meet the national minimum competencies. The results from the exam show that there are still weaknesses in the areas of communication, professional ethics, information management and clinical skills.(2)
Our internal survey also revealed dissatisfaction of faculty alumni and staff on the competence of recent graduates in the areas of communication, biomedical sciences, information management and clinical skills.(3)
In 2012, the Council revised the competency standards to emphasize generic skills and the foundation of biomedical sciences. The revision also added detailed learning objectives. This led to some institutions revising their curriculum to strengthen the biomedical sciences and generic skills.(4)
Quality assurance system is implemented through both an internal and external approach. Only few well-established medical schools have implemented an internal quality assurance system. Most schools use the external quality assurance coordinated by the National Agent of Accreditation. Currently, only 16 of the 76 medical schools in Indonesia have achieved the highest accreditation grade.(5)
Although there is still dissatisfaction with the curriculum changes among several physiology teachers, physiology has proven more adaptable other branch of biomedical sciences. Most institutions have adopted an organ-system curriculum design, where the physiological concepts of integration, control and feedback are strongly represented in the competency based curriculum.
Key words: Competency-based curriculum, quality assurance, implementation.

Is competency-based education the way forward in the Middle East?

M.M. Subhan

Physiology, Arabian Gulf University, Manama, Bahrain

The Middle East comprises of approximately 15 nations and refers to the area between Arabia and India, mainly the nations of the Persian Gulf. Although a form of competency-based medical education was present centuries ago in this region, this discussion will cover recent information about modern physiology and medicine in this region.
The oldest centre for modern medical training in the Middle East was started in 1867 in Lebanon, and this is now known as the American University of Beirut. Within the six Gulf Cooperative Council (GCC) states, Saudi Arabia has the oldest medical college, King Saud University (KSU, 1967). The current levels of competency-based physiology education in the curricula at KSU and the Arabian Gulf University; a regional GCC uni-

versity based which started in Bahrain in 1982, and other universities in the Middle East will be presented.
Around 2002, the Accreditation Council for Graduate Medical Education (ACGME) in the USA identified six general competencies to assess resident competence. The World Federation for Medical Education endorsed these. The World Federation for Medical Education has produced a document 'Basic Medical Education WFME Global Standards for Quality Improvement'. It was produced in 2003 and revised in 2012, with an aim to set international standards to all medical schools and also encourage reform. The present state of physiology education will be discussed in the light of these standards.
More specific to the Middle East, the Arab Knowledge Report 2009, although positively showing a consistent decline in illiteracy in the region, also paints a worrying picture for universities in the region. This report was co-produced by the Mohammed bin Rashid Al Maktoum Foundation and the United Nations Development Programme/Regional Bureau for Arab States.
Whether competency-based education (CBE) in physiology and other medical sciences will improve or worsen the situation described by the Arab Knowledge Report 2009 will be discussed. This matter is also complicated by the fact there has been an exponential establishment and growth by 400 % of Departments of Physiology in the Middle Eastern region over the last 2 decades. Due to this expansion, CBE has taken a back seat in terms of present teaching priorities for physiologists and administrators in the region. Eventually, physiologists have to match student competencies with the needs of patients and stakeholders, in a new era of globalization and interdependence.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The evolution of the vertebrate heart: functional and phylogenetic insights

J.W. Hicks[1] and T. Wang[2]

[1]Ecology and Evolutionary Biology, University of California Irvine, Irvine, CA, USA and [2]Department of Bioscience - Zoophysiology, Aarhus University, Aarhus, Denmark

The emergence of the four-chambered heart and its underlying substructures was a critical event in vertebrate evolution, appearing at least twice independently; once in the vertebrate group that gave rise to crocodilians and birds (archosaurs), and once in the ancestral group of mammals (synapsids). A fully divided ventricle provides for the ability to maintain high cardiac outputs and systemic arterial blood pressures, while simultaneously keeping low blood pressures within the pulmonary circulation. Low pulmonary blood pressures allow for a thinner blood-gas barrier within the lungs, an important component of overall higher pulmonary diffusion capacity and hence more efficient gas exchange. In addition, a fully divided ventricle also avoids the mixture of oxygen-rich and oxygen-poor blood within the heart. These characteristics are both necessary for supporting increased rates of metabolism, which is directly linked with the rapid expansion and success of mammals and birds (Hicks and Wang, 2012).
Inferences about cardiac evolution result from studies investigating comparative cardiac morphology and function in extant species. Although extant reptiles (turtles, lizards, snakes and crocodilians) are only distantly related to modern mammals and birds, this clade provides the best group of animals for investigating and ultimately understanding the evolution of the four-chambered heart.
The heart of non-crocodilian reptiles has two anatomically divided atria, and a single ventricle. Between the many species of reptiles, the internal morphology of the ventricle exhibits a large degree of variability, with many folds and septae. Regardless of the anatomical variability within the ventricle, a functional characteristic of the heart within all non-crocodilian reptiles is the potential for the mixing of oxygen rich blood and oxygen poor blood (cardiac shunting). Cardiac shunting is defined by its directionality, with right-to-left shunts (R-L) being defined as a portion of systemic venous blood bypassing the lungs and reentering the systemic circulation. Alternatively, a left-to-right (L-R) shunt represents pulmonary venous blood (oxygen rich) recirculating back to the lungs. Emerging from the single ventricle are the three great vessels; the pulmonary artery, the left aortic arch (LAo) and right aortic arch (RAo) (Hicks and Wang, 2012).
It is interesting to note that crocodilians evolved a four-chambered heart, similar to birds and mammals. However, even in these animals, the separation of the pulmonary and systemic circulations is not absolute. Crocodilians retain the ancient phenotype of dual aortae (LAo and RAo), with the LAo emerging from the right ventricle, along with the pulmonary artery. The RAo exits the left ventricle. This unique anatomical arrangement results in the capacity for portion of the systemic venous blood to bypass the lungs and reenter the systemic circulation (right-to-left shunt) (Hicks and Wang, 2012).
In the latter half of the 20th century, many comparative cardiovascular physiologists argued that cardiac shunts were an adaptive trait in non-avian reptiles. Basically it was reasoned; why would reptiles maintain such a unique cardiac morphology and shunting capacity if such traits were not adaptive? This view resulted in a number of hypotheses about the adaptive advantages of cardiac shunting (see Hicks and Wang, 2012 for review). However experimental support for an adaptive significance of cardiac shunting in non-avian reptiles has been lacking.
For physiological or morphological trait to be considered adaptive it is important to provide evidence that the absence of the trait actually reduces physiological performance and/or reproductive fitness. Lacking such evidence, it is just as likely, that the unique features and functions of the reptilian heart is simply an embryonic or ancestral character; a character that does not negatively impact overall animal fitness and therefore has not been selected against. However, quantifying genetic fitness in reptiles is nearly impossible. Consequently the "adaptiveness" of cardiac shunts and determining the factors that drove the evolution of the four chambered heart and its characteristic structures, must be inferred by using a strategy that takes advantage of a variety of analytical and experimental approaches. Several of these approaches will be discussed in this symposium.

Hicks, JW and Wang, T (2012) The functional significance of the reptilian heart: new insights into an old question. In: Ontogeny and Phylogeny of the Vertebrate Heart. ed. D. Sedema and T. Wang, Springer-New York, pg. 207-227.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA105

Transcription factors regulate cardiac septum formation in the vertebrate evolution

K. Koshiba-Takeuchi[1], S. Kawakami[1], H. van Weerd[1,2], N. Yokota[1], Y. Moriyama[1] and J.K. Takeuchi[1]

[1]IMCB, The University of Tokyo, Tokyo, Japan and [2]University of Amsterdam, Amsterdam, Netherlands

Vertebrates have been modified cardiac morphologies and abilities to adapt terrestrial life with the use of lung for breathing in the evolution. The hearts morphologies have been more sophisticated and complicated from fish to mammals; fish have simple two-chambered heart (one atrium and one ventricle), amphibians have three-chambered (two atria and one ventricle), and crocodilian, birds, and mammals have four-chambered (two atria and two ventricles) heart. Interestingly at early stages mammalian heart forms a turning tube like as fish heart. Then we thought that to know the molecular mechanism of heart evolution leads to elucidation of developmental mechanism of cardiac septal formation and of congenital disease occurred in cardiac septa.
Non-crocodilian reptiles hold a unique place in the evolution of the heart, as their ventricle chambers are apparent intermediates between three-chambered heart and four-chambered heart. The previous study indicated that a steep and correctly positioned Tbx5 gradient is important for ventricular septum formation by using reptiles and the transgenic mice in which Tbx5 expressions like as reptiles. Sarcopterygians, including lungfish and coelacanth, also sit on the unique position between two-chambered heart (fish) and three-chambered heart (amphibian), suggesting that sarcopterygian is quite useful for studying about atrial septum formation. We constructed 3D images of lungfish and coelacanth hearts to observe the inside structure in detail. As a result, coelacanth heart is still similar to the fish, but lungfish has very sophisticated septated heart both in atria and ventricles. In this session we want to present when and how atrial septum is formed in vertebrate evolution via lungfish heart development comparing fish and amphibians.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA106

Development of the cardiac building plan

A.F. Moorman

Anatomy, Embryology & Physiology, AMC, Amsterdam, Netherlands

Molecular and genetic studies around the turn of this century have revolutionized the field of cardiac development. We now know that the primary heart tube, as seen in the early embryo contains little more than the precursors for the left ventricle, whereas the precursor cells for the remainder of the cardiac components are continuously added, to both the venous and arterial pole of the heart tube, from a single centre of growth outside the heart. While the primary heart tube is growing by addition of cells, it does not show significant cell proliferation, until chamber differentiation and expansion starts locally in the tube, by which the chambers balloon from the primary heart tube. The transcriptional repressors Tbx2 and Tbx3 locally repress the chamber-specific program of gene expression, by which these regions are allowed to differentiate into the distinct components of the conduction system. Molecular genetic lineage analyses have been extremely valuable to assess the distinct developmental origins of the various component parts of the heart, which currently can be unambiguously identified by their unique molecular phenotype.

Evolution of the building plan of the heart

B. Jensen[1,2], B.J. Boukens[2], T. Wang[1], A.F. Moorman[2] and V. Christoffels[2]

[1]Biosciense, Aarhus University, Aarhus C, Denmark and [2]University of Amsterdam, Amsterdam, Netherlands

In the hearts of mammals and birds, a system of nodes and fast-conducting tissues govern the activation pattern that induces myocardial contractions. We have previously shown that the atrioventricular conduction axis, consisting of the atrioventricular junction and the ventricles, is evolutionary conserved. From fish to man, the embryonic heart is patterned into compartments by the same genes. It has a muscular and slow conducting atrioventricular canal (Tbx2/3 positive) and a spongy ventricle (Cx40 and Anf positive) that serves the dual purpose of fast conduction and contraction. This design is maintained in fishes, amphibians and reptiles, whereas mammals and birds develop a fibrous insulating plane, thick compact ventricular walls and septum and, hence, form a discrete ventricular (His-Purkinje) conduction system from the embryonic spongy ventricle. Our understanding of the cardiac pacemaker, seen as a sinus node in mammals, is less clear. Most vertebrates have myocardium upstream of the right atrium (atrium in fishes) called the sinus venosus. It remains disputed if the dominant pacemaker of the heart is a property of the sinus venosus in entirety or of a specialised subset of sinus venosus myocardium. In the anole lizard the sinus venosus consists of three sinus horns that together equal the size of the right atrium. We investigated the electrical activation of the sinus venosus with optical mapping. Activation was earliest in the posterior sinus horn and then spread to the anterior sinus horns both of which are guarded by valves at the sinus-venous border. Later, the atria were activated from the dorsal sinu-atrial border, where the sinus node of mammals and birds is located. This region expressed the conserved sinus node markers Isl1 and Tbx3. We conclude that chambers and border regions of the vertebrate heart have highly similar patterns of gene expression and phenotypes, and that the cardiac conduction system simply follows from this building plan. Consequently, modifications rather than novelties characterise cardiac evolution.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA108

The evolving role of the cardiac sarcoplasmic reticulum

H. Shiels

Life Sciences, University of Manchester, Manchester, UK

The fundamental principles of excitation-contraction coupling are highly conserved between vertebrate species. However, the role of one organelle in particular, the sarcoplasmic reticulum (SR), is highly variable among species, tissue-type, age and environmental conditions, and has been linked to heightened cardiac performance and numerous cardiac pathologies. The SR is a specialised form of endoplasmic reticulum found in muscle cells that provides an intracellular reservoir of calcium. SR calcium can be rapidly mobilised and released from the SR for contraction, and re-sequestered back into the SR for relaxation. In mammals, this intracellular calcium flux pathway is essential for normal cardiomyocyte excitation-contraction coupling. The role of the SR is more contentious in non-mammalian vertebrates with some species recruiting little or no calcium from the SR during excitation-contraction coupling. While most studies suggest athletic ectotherms rely more strongly on SR calcium cycling, phylogenetic investigations suggest other factors may be important, and environmental conditions are also major determinants. This talk will discuss the enigmatic role of the SR during the evolution of the four-chambered heart drawing on comparative studies across vertebrates.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA109

The Hawaiian bobtail squid as a model organism for studying host/microbe interactions

S. Nyholm

Molecular and Cell Biology, University of Connecticut, Storrs, CT, USA

The establishment and maintenance of the light organ symbiosis between the Hawaiian bobtail squid Euprymna scolopes and the bioluminescent bacterium Vibrio fischeri depends on selection of V. fischeri and exclusion of non-symbiotic bacteria from the environment. Successful colonization of the host and cell-cell signaling between the partners triggers a morphogenetic program that leads to maturation of the association. Subsequent physical, biochemical and immunological mechanisms help to ensure that host-symbiont specificity is maintained. Current evidence suggests that the host's cellular innate immune system, in the form of macrophage-like hemocytes, assists in mediating host tolerance of V. fischeri. To further understand the role of hemocytes in this association, we have used both transcriptomic and proteomic analyses of this cell type. We have identified a number of pattern receptors involved with the recognition of microbe-associated molecular patterns. Among these was a complete open reading frame to a novel peptidoglycan recognition protein (EsPGRP5) with conserved residues for predicted amidase activity. Other transcripts and proteins identified included members of the conserved NF-κB signaling pathway, predicted members of a complement-like pathway, the carbohydrate binding protein galectin and a putative cephalotoxin. Quantitative PCR of complement-like genes, cephalotoxin, EsPGRP5, and a nitric oxide synthase showed differential expression in circulating hemocytes isolated from adult squid with colonized light organs compared to those from cured hosts. These data suggest that light organ colonization influences gene expression of the cellular innate immune system of the host. Studies are currently underway to determine how hemocytes distinguish between V. fischeri and non-symbiotic bacteria in both juveniles and adults. In addition to the light organ symbiosis, female squid have, as part of their reproductive system, an accessory nidamental gland (ANG) that houses a bacterial consortium within epithelia-lined tubules. We have used a number of microscopy and molecular techniques to identify dominant members, including the Rhodobacterales (Phaeobacter spp.) and Verrucomicrobia. 16S rRNA fluorescent in situ hybridization revealed that many ANG tubules were dominated by specific bacterial taxa, such as Rhodobacterales, Verrucomicrobia or Cytophaga-Flavobacteria-Bacteroidetes. Our data also suggest that bacteria from the ANG are deposited directly into the jelly coat of freshly laid eggs. To begin to explore the function of the ANG bacterial consortium, we conducted a series of experiments whereby development of egg clutches (with and without antibiotic treatment) was monitored over a four-week period. Treated eggs developed a thick fungal biofilm that resulted in the death of the embryos. A fungal culture was isolated from this biofilm and morphological characterization and multi-locus sequence typing suggest that it is a haplotype of the Fusarium solani species complex, a group that includes pathogens of marine animals. Taken together, these data suggest ANG bacteria may protect developing squid embryos from fungal biofilms, similar to what has been described for bacterial egg protection of other marine invertebrates. Overall, E. scolopes offers the unique opportunity to study both a binary (light organ) and consortial (ANG) bacterial association in the same host.

Genomic evidence for the evolution of physiological robustness in coral-algal symbiosis

M. Weber[1,2], R. Iglesias-Prieto[2], H. Kitano[3] and M. Medina[1]

[1]School of Natural Sciences, UC Merced, Merced, CA, USA, [2]Unidad de Sistemas Arrecifales Instituto de Ciencias del Mar y Limnología, UNAM, Puerto Morelos, Q. Roo, Mexico and [3]Systems Biology Institute, Tokyo, Japan

We explored coral gene expression patterns and the physiological response of their dinoflagellate symbionts (*Symbiodinium*) to temperature stress. Fragments of *Montastraea faveolata* were field-collected in the Mexican Caribbean during summer (2012) and winter (2011) seasons. For each seasonal experiment, the corals were acclimated to 28degC under controlled tank conditions. Half of the fragments were kept in the controlled 28degC conditions and half were increased to 32degC for ten days. Subsequently the treatment corals were returned to 28degC and allowed to recover for up to six weeks. The same protocol was used for two different experiments in winter and summer. After ten days of thermal stress, we

observed break down of symbiosis (bleaching) in the summer experiment. The symbiosis was robust in corals collected for the winter experiment, despite exposure to equivalent stress.
We analyzed host transcriptome response to temperature stress. Several cellular pathways appeared to contribute to holobiont robustness. Corals differentially express a variety of enzymes that react with reactive oxygen species produced by stressed algal symbionts. Genes with functions attributed to calcium ion regulation and cell-cell adhesion are also differentially expressed before activation of the cell death pathways that cause symbiosis breakdown. We measured clear physiological differences in resident *Symbiodinium* populations between winter vs. summer experiments suggesting that the regulation of dinoflagellate physiology also contributed to holobiont robustness. We will discuss the host transcriptome response, organismal performance and the evolution of holobiont tolerance to thermal stress associated with these physiological differences. We will use this case study to discuss a theoretical model of biological robustness for the coral-algal holobiont.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Role of light and multiple scattering on the establishment of mutualistic relationship with photosynthetic organisms

S. Enríquez

Unidad Académica de Sistemas Arrecifales Puerto Morelos, Universidad Nacional Autónoma de México, Cancún, Quintana Roo, Mexico

On the pigment-protein complexes, antenna, of the photosynthetic membranes relies the capacity of the primary producers to collect solar radiation and to transfer the excitation energy to the reaction centre of the two photosystems, where takes place its transformation into chemical energy. In order to favour an efficient excitation transfer and a continuous flow of electrons, evolution has generated a large diversity of antenna collectors, which also must photoprotect the photosynthetic apparatus from the excess of energy absorbed through the formation of "quenchers". Efficient excitation transfer has been achieved at expenses of reducing pigment ability to collect light. A phenomenon called "packaging effect" identified first for oceanographers while describing the variability in the inherent optical properties of phytoplankton, has found that photosynthetic pigments organized in alive structures are very inefficient to collect light due to self-shading. Multiple scattering of light has allowed counterbalancing the packaging effect, thanks to the enhancement in pigment absorption produced by the enlargement of the photon optical path. Multiple scattering, then, has mediated the design of a large biological diversity of solutions all of them led to the generation of efficient solar energy collectors. The establishment of mutualistic relationships with non-photosynthetic organisms able to supply scatting structures can also be explained by the capacity of multiple scattering to increase the photosynthetic performance of the new holobiont optimizing the use of the limiting resources. Here are presented a few examples of successful symbiotic relationships between invertebrates and algae, where the ability of (1) the highly reflective aragonite surfaces of the coral skeleton, or (2) the sponge silica spicula have allowed the appearance of the most efficient light collectors in nature, and explains the evolutionary and ecological success of these extremely efficient symbiotic relationships. This comparative study also highlights the capacity of multiple scattering to explain the origin itself of multicellularity in photosynthetic organisms.

Individuality and temporal stability of the human gut microbiome

S. Sunagawa[1], S. Schloissnig[1], M. Arumugam[1], M. Mitreva[2], J. Tap[1], A. Zhu[1], A. Waller[1], D.R. Mende[1], J.R. Kultima[1], J. Martin[2], K. Kota[2], S. Sunyaev[3], G.M. Weinstock[2] and P. Bork[1]

[1]EMBL, Heidelberg, Germany, [2]The Genome Institute, Washington University School of Medicine, St Louis, MO, USA and [3]Harvard Medical School, Boston, MA, USA

The human body typically harbors about 100 trillion cells of microbial origin - commonly referred to as the human microbiome - the vast majority of which resides in the gastrointestinal tract (Savage 1977). While studying the extent of human genetic variation, for example in the 1,000 genomes project (The 1000 Genomes Project Consortium, 2010), and the understanding of its practical impact have advanced rapidly, the genetic variation of the human microbiome has remained largely unexplored. One of the reasons is attributed to the difficulty in cultivating the multitude of microbial species that inhabit our intestines. The possibility to high-throughput sequence DNA directly isolated from the environment has revolutionized the study of microbial communities, but analyzing single nucleotide polymorphisms (SNPs) in mixed microbial populations has remained a challenge. We therefore developed a methodological and statistical framework for metagenomic variation analysis and applied it to published sequencing data derived from 252 faecal samples of 207 European and North American individuals (The Human Microbiome Project Consortium 2012 and Qin et al. 2010). Exploiting the information generated by aligning 7.4 billion Illumina reads to 101 reference species, we detected 10.3 million single nucleotide polymorphisms (SNPs), almost as many as have been identified in humans so far.
Population variation of gut microbial communities with accompanying changes in species abundances over long time periods have not been studied yet in large cohorts. It has been unclear if host-specific strains are retained over time or constantly replenished via the environment. To address this question, we used 88 gut metagenomes collected from 43 healthy

subjects that were sampled at least twice over time intervals of up to 1 year and measured population similarities of dominant gut species using fixation indices (FST). The most striking result was that subjects sampled at varying time intervals exhibited individuality and temporal stability of SNP variation patterns, despite considerable composition changes of their gut microbiota. This indicates that individual-specific strains are not easily replaced and furthermore, that an individual may have a unique metagenomic genotype, which may also imply gut physiological individuality and consequences for personalized diet or drug intake.

Endophytic bacteria in plant meristems: a new type of mutualistic symbiosis

A. Pirttilä, J.J. Koskimäki and J. Pohjanen

Biology, University of Oulu, Oulu, Finland

We have identified a unique symbiotic plant-endophyte association in the meristematic tissue of Scots pine buds, where *Methylobacterium* spp. are the dominant species. These microbes are found in the cells of the apical meristem, needle and scale primordia, and around the resin ducts. Throughout the year they are associated with growing tissues (Pirttilä *et al.* 2000, 2005). Infection of pine seedlings by the endophytic strain *Methylobacterium extorquens* sp. DSM13060 induces expression of several PR-like genes, along with genes associated with development and signaling, such as *HYL1* and *ALE2*, a receptor protein kinase, and *CYP71*. A group of genes associated with development and apoptosis such as *AMP1*, *MERI5*, *AGL8*, *COW1*, plantacyanin, and chlorophyllase are down-regulated in the *M. extorquens* -infected seedlings. We have isolated endophytic products that increase viability of pine tissue *in vitro* (Pirttilä *et al.* 2004) and characterized some of them as antioxidants. When *M. extorquens* sp. DSM13060 was tagged with fluorescent proteins expressed by endophyte-specific promoters, the colonization with respect to specific metabolic processes could be observed in Scots pine seedlings. Furthermore, we saw that *M. extorquens* sp. DSM13060 specifically enters the plant through the plant epiderm by the crack entry and/or active penetration and forms infection pockets, resembling rhizobial infection. Unpublished data indicates that meristem-associated endophytes likely exist in other plant species. The shoot meristems can be considered among the most important tissues of the plant, responsible for growth and development of new leaves and stems. The finding of bacterial endophytes in these tissues suggests that a balanced interaction is essential for their proper function. As endophytes have been occupying the plant interior for more than 400 million years (Krings *et al.* 2007), mutual evolution must have driven ways to subsist, adapt, and eventually refine the interaction to a balanced state.

SA114

Muscle protein and strength retention by bears during winter fasting and starvation

H.J. Harlow

Zoology & Physiology, University of Wyoming, Laramie, WY, USA

In the 1960s Cahill defined fasting in 3 phases with Phase II as fat using and protein conserving which is extended by animals adapted to long-term fasts without detrimental effects. Hibernation is a form of extreme fasting and black bears, Ursus americanus, undergo 5 months where they do not eat, drink, urinate or defecate while the body temperature is maintained only 5°C below normal. To accomplish this, they have a high hypothalamic set-point for fall hyperphagia and large fat reserve with a high proportion of polyunsaturated fatty acids. During transition to phase II there is elevated leptin, enhanced gut flora, decreased thyroxin and declining urea:creatinine ratios which together represent a period of fall "walking hibernation". The inhibitory effect of leptin on neuropeptide Y from the arcuate nucleus may initiate the onset of anorexia and the bear's entrance into their winter den. Bears are relatively unique in that they undergo pregnancy and lactation while fasting. There is 47% greater fat and 26% greater protein deposition for reproductive bears in the fall to offset their greater rate of mass and energy loss during denning. Long-term fasting in obese humans results in cardiac muscle protein loss and dysfunction, however, echocardiographic images of bears revealed no left ventricular resculpturing or reduced thickness during winter inactivity and chronic hypotension. Bears showed dramatic respiratory sinus arrhythmia with long pauses between breaths and profoundly depressed heart rates as low as 4 bpm. Accelerated heart rate during inhalation enhances oxygen transport within the heart tissue while the period of dramatically reduced heart rate acts to minimize energy expenditure and conserve cardiac protein. Skeletal muscle biopsies were taken from the biceps femoris, gastrocnemius and vastus lateralis during early and late denning. There was no loss of number, cross sectional area of fibers or marked transition of SO to FG fibers. Denning bears lost only about 0.03% protein/day, a value that is an order of magnitude below that reported for rats and humans, perhaps due to high ketone body inhibition of gluconeogenesis associated with a low thyroid activation of proteolysis and low urea:creatine ratio. This conservation of morphology and protein is atypical of starvation or disuse-induced skeletal muscle atrophy models. Bears underwent a period of skeletal muscle protein accretion with synthesis rates 1.4 times higher than degradation during the

summer. Rates of synthesis and breakdown decreased 60-70% from summer to fall during the "walking hibernation" transition period with a concomitant 30-60% drop in RNA, a decreased ratio of RNA to DNA and an elevated δ 15N value in skeletal muscles. But all parameters then remained unchanged throughout the 5 months of denning without food or water. However, not all muscle behaves identically during fasting. There was a 4-11% loss of protein from the gastrocnemius and biceps femoris muscle by lactating bears but no loss from the vastus lateralis. Protein synthesis could occur in a selected muscle if amino acids are made available by the marginal degradation of other skeletal muscles in concert with proteolysis of organs, collagen and smooth muscle. The collagen metabolites hydroxyproline and glycine were elevated in denned bears. In addition, proteolysis of kidney tissue releases large amounts of serine that was high in late winter. The gastrointestinal tract may also be a labile protein source as seen in an elevation of blood alpha amino acids. Winter protein demands during the Phase II fast are further reduced by: 1) no winter arousal bouts, 2) delayed implantation for pregnant females, 3) no fur growth and 4) urea nitrogen salvaging (UNS) to avoid urinary nitrogen loss. Bears recycle almost 100% of their urea, perhaps due to UTB urea transporters in the bladder and intestines which salvage urea for microbial hydrolysis in the intestine. The resulting ammonia is transported to the liver where it is reamminated into new amino acids and muscle protein. UNS is upregulated in hibernators 10-40 fold during fasting and torpor as shown by 15N labeled urea studies. Bears exhibit subtle EMG patterns throughout the denning period with peripheral vasodilation which may disperse heat and facilitate wound healing. As a result of conserved protein, fiber morphology and isometric/isotonic contraction patterns, bears during 150 days of confinement and complete food deprivation exhibit only marginal loss of strength. Muscle performance measured both in vivo and in vitro declined only 23% from early to late winter compared to a 70% loss predicted for humans confined to a hospital bed (inactive but well fed) for 150 days. Bears are truly adapted long-term fasters.

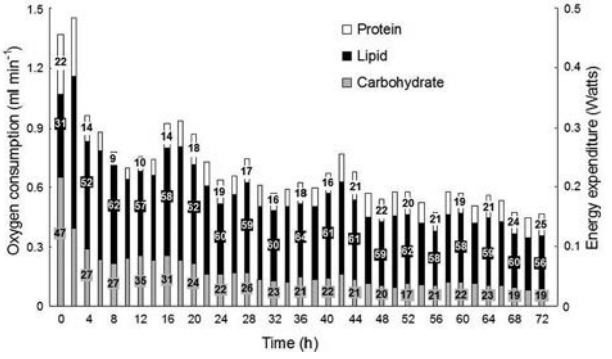
Direct measurements of substrate oxidation using 13CO2 breath testing reveals shifts in fuel mix during starvation

M.D. McCue

Biological Sciences, St. Mary's University, San Antonio, Texas, UK

Fasting animals are believed to sequentially switch from utilizing one metabolic substrate to another in the order of carbohydrates, to lipids, then to proteins. The timing of these physiological transitions are traditionally estimated using indirect measures of substrate oxidation including, changes in RER, blood metabolites, or respiratory enzyme activities. Here we show that the oxidation of distinct nutrient pools in the body (lipids, proteins, and carbohydrates) that are gradually enriched in 13C can be directly quantified using 13CO2-breath testing. Seventy-two Swiss Webster mice were raised to adulthood on diets supplemented with 13C-1-L-leucine, 13C-1-palmitic acid, 13C-1-D-glucose, or no tracer. Mice were then fasted for 72 hours during which VO2, VCO2, δ13CO2, body temperature (Tb), and blood metabolites (i.e., glucose, ketone bodies, and triacylglycerides) were continually measured. The fasting mice exhibited reductions in Tb (4.6°C), body mass (29%), BMR (24%), and RER (0.18), and significant changes in blood metabolites, but these responses were not useful to clearly identify specific changes in fuel mixture. Direct measurements of endogenous nutrient oxidation by way of 13CO2-breath testing revealed a rapid crash in the rate of oxidation of carbohydrates from 47% to 27% of the total energy expenditure during the first 6 hours without food. This response was mirrored by a coincidental increase in rate of endogenous lipid oxidation from 31% to 52%. A final transient peak in carbohydrate oxidation occurred between 8-18 hours indicating the transition between Phase I and II. A period of protein sparing between 8-12 hours was observed where endogenous protein oxidation accounted for as little as 9% of the total energy expenditure. Thereafter, protein oxidation continually increased accounting for as much as 25% of the total energy expenditure by 72 hours, suggesting that these mice exhibit a gradual, not an abrupt, transition from Phase II to III. This study demonstrates that direct measurements of substrate oxidation address a gap in our understanding of the timing and magnitude of sequential changes in substrate oxidation that occur during prolonged fasting and starvation.



How a mouse oxidizes different types of endogenous nutrients to meet its energy demands during prolonged fasting.

Differential mobilization and use of fatty acids during fasting

T.G. Valencak[1,2] and E.R. Price[3]

[1]University of Veterinary Medicine Vienna, Vienna, Austria, [2]Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing, China and [3]University of Wisconsin - Madison, Department of Forest and Wildlife Ecology, Madison, WI, USA

Fatty acids and particularly, polyunsaturated fatty acids are essential constituents of biological membranes. Apart from this, they fulfil functions as signalling molecules, anti- freezing compounds and energy storage. While a lot of research has been conducted on the changes in lipid content that occur during fasting, only few studies have focused on changes in the quality of body lipids.

During fasting and any extended period of diminished energy intake such as starvation, the fatty acid composition of the lipids is altered: fat mobilisation, transport and oxidation all work together and induce an apparent "fasting fatty acid response" with saturated fatty acids being largely retained whereas monounsaturated and polyunsaturated fatty acids

are largely mobilised and thus decreased in stored triacylglycerols.
In the presentation, this pattern will be explained in more detail in a variety of animals in the light of the existing literature on the subject. We will examine changes in whole- animal, adipose and muscle fatty acid composition that occur during fasting/starvation. We will also discuss the selective retention of C 18:2 n-6 in white adipose tissue of hibernating animals that seems to be related to physiological heterothermy and not starvation per se.
We conclude that the observed changes in fatty acid composition are unlikely to represent an adaptive "starvation response". While triacylglycerols seem to change in an unregulated manner in response to fasting and starvation, membrane fatty acid composition is changed more systematically when an animal is restricted calories. Future research might shed light on this subject and should emphasise the separation of lipid fractions (triacylgylcerols vs. phospholipids) in the various tissues.

Alternate day fasting: a novel dietary restriction regimen for weight loss in humans

K.A. Varady

Kinesiology and Nutrition, University of Illinois, Chicago, Chicago, IL, USA

Background: The ability of modified alternate day fasting (ADF) (i.e. consuming 25% of energy needs on the fast day, and ad libitum fed on feed day) to facilitate weight loss and lower vascular disease risk in obese individuals remains unknown. Objective: This study examined the effects of ADF, administered under controlled versus self-implemented conditions, on body weight and coronary heart disease (CHD) risk indicators in obese adults. Design: Sixteen obese subjects (12 women/4 men) completed a 10-week trial, consisting of 3 phases: 1) 2-week control phase, 2) 4-week weight loss/ADF controlled feeding phase, and 3) 4-week weight loss/ADF self-selected feeding phase. Results: Dietary adherence remained high throughout the controlled feeding phase (86% days adherent), and the self-selected feeding phase (89% days adherent). Rate of weight loss remained constant during controlled feeding (0.67 ± 0.1 kg/week) and self-selected feeding phases (0.68 ± 0.1 kg/week). Body weight decreased ($P < 0.001$) by 5.6 ± 1.0 kg (5.8% ± 1.1%) after 8 weeks of diet. Percent body fat decreased ($P < 0.01$) from 45 ± 2% to 42 ± 2%. Total cholesterol, LDL cholesterol, and triacylglycerol concentrations were lowered ($P < 0.01$) by 21 ± 4%, 25 ± 10%, 32 ± 6%, respectively, after 8 weeks of ADF, while HDL cholesterol remained unchanged. Systolic blood pressure decreased ($P < 0.05$) from 124 ± 5 mm Hg to 116 ± 3 mm Hg. Conclusions: These findings suggest that ADF is a viable diet option to help obese individuals lose weight and decrease CHD risk.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA118

Thermoregulatory adaptations to starvation and cold in birds

E. Hohtola

Department of Biology, University of Oulu, Oulu, Finland

As endothermic animals, birds allocate a significant part of their energy intake for maintaining homeothermy, especially in cold environments. Their body temperatures and metabolic rates are typically higher than in mammals of similar body mass. Therefore, food shortage and starvation pose a true energetic challenge for maintaining homeothermy in birds (McCue 2010). As most birds are small, their energy reserves in relation to metabolic rate are limited, which together with high surface-to-volume ratios exacerbates the effects of starvation.
During food shortage, energy can be saved if the need for active thermogenesis can be reduced. Such a hypometabolic state can be achieved by increasing thermal insulation beyond the level found in fed birds or by reducing body temperature in a regulated manner or by combining the two mechanisms. Even in fed state, birds increase their insulation during the rest phase of the daily cycle. This is done mainly by ptiloerection and postural adjustments and there is probably not very much extra insulation available by these mechanisms in fasting birds. However, a significant decrease in heat loss can be achieved by regional heterothermia, where peripheral parts of the body are allowed to cool and only the core parts are held normothermic. Although this phenomenon is known from other physiological situations, it has not been studied extensively in fasting or food-restricted birds.
A general decrease in core body temperature will naturally decrease the metabolic burden of homeothermy. More and more evidence for a capability to a regulated decrease of body temperature (rest-phase hypothermia, shallow torpor) during starvation in birds is accumulating (McKechnie & Lovegrove 2002). The decline of body temperature in shallow torpor is typically 3–10°C. While deep torpor triggered by starvation or even without energetic stress has been recognized for a long time in some avian groups (e.g., in humming-birds and swifts), recent studies show that basically all avian groups can save energy by entering starvation-induced shallow torpor during the rest-phase of their daily cycle. In deep torpor, birds lose their responsiveness to environmental stimuli, whereas in shallow torpor the react to external disturbances, which has implications ion vigilance and predator avoidance. So far, deep or shallow torpor has been found in at least 11 avian orders and 29 families.
The metabolic savings in shallow torpor are obviously smaller than in deep torpor. The reduction in metabolic rate is, however, often larger than predicted by the decline in deep-body temperature (Hohtola 2012). This suggests that fasting birds are able to recruit otherwise unused insulative mechanisms. Regional heterothermy in peripheral tissues is one possibility, although it has not been studied in detail. It would save energy by two mechanisms: 1) By making the temperature gradient between body core and the environment less steep (resulting in lower conductance) and 2) By lowering thermostatic costs of the peripheral parts at lower tissue temperature.

The thermoregulatory adjustments during fasting are tuned to the amount of remaining energy reserves. Thus, nocturnal hypothermia is deeper in birds that roost at lower body mass (Reinertsen 1996) and hypothermia is deeper on each successive fasting day during prolonged fasting (see Hohtola 2012). How starvation is translated to a neurohumoral thermoregulatory signal that results in a lower regulated body temperature and metabolic savings is, however, not known. These mechanisms, together with the observed large energy savings ensuing from the relatively small decline in body temperature warrant further studies on fasting-induced thermoregulatory adaptations.

The adventitia: a dynamic interface containing resident progenitor cells

M. Majesky[1,4], X. Dong[4], V. Hoglund[4] and W. Mahoney[2,3]

[1]Pediatrics, University of Washington, Seattle, WA, USA, [2]Pathology, University of Washington, Seattle, WA, USA, [3]Institute for Stem Cell & Regenerative Medicine, University of Washington, Seattle, WA, USA and [4]Seattle Children's Research Institute, University of Washington, Seattle, WA, USA

Recent observations suggest that the outer layer of blood vessel walls, the adventitia, exhibits properties of a stem/progenitor cell niche. Stem cell antigen-1 (Sca1)/CD34-positive progenitor cells have been isolated from the adventitia of both murine and human arteries and veins with potentials to form smooth muscle cells (SMCs), pericytes, macrophages, osteogenic cells and adipocytes. These progenitors cluster at or near the border zone between the outer media and inner adventitia. In the mouse this border zone region corresponds to a localized site of sonic hedgehog (Shh) signaling in the artery wall. The onset of Shh signaling corresponds to termination of SMC layer formation in developing arteries and the appearance of adventitial Sca1-positive (AdvSca1) cells around E15.5. Shh acts as a mitogen and survival factor for AdvSca1 cells ex vivo and many fewer Sca1-positive cells are found in the adventitia of Shh-null embryos in vivo. AdvSca1 cells form pericytes and macrophages in matrigel implant angiogenesis assays in vivo. The role of AdvSca1 cells in growth, remodeling and disease of blood vessels and surrounding tissues will be discussed.

Enhancing stem cell recruitment within the microcirculation - chemokines, chemicals and caveats

D.P. Kavanagh, A.I. Yemm, R.L. White and N. Kalia

College of Medical and Dental Sciences, University of Birmingham, Birmingham, West Midlands, UK

Considerable interest surrounds the use of stem/progenitor cells (SCs) in tissue regeneration and repair. A variety of potential therapeutic cell types have been identified, including adult bone marrow (BM)-derived haematopoietic (HSC) and mesenchymal stem cells (MSC). Experimental studies suggest that HSCs and MSCs are able to alleviate inflammation and subsequently contribute to tissue repair. Local recruitment of injected SCs by the microcirculation of injured tissue is a likely prerequisite for repair. Limited recruitment of SCs subsequent to systemic infusion has been partly used to explain the poor clinical success of cellular therapy. The molecular adhesive mechanisms that underpin SC recruitment and retention in injured tissue remain poorly understood. Understanding these mechanisms may allow identification of strategies that can enhance SC recruitment and may improve the efficacy of SC-based therapies.

HSCs express a variety of surface adhesion molecules (e.g. CD49d, CD18, CD44) that are important in mediating their recruitment to injured tissues. Our intravital microscopy studies, conducted on different murine organs, demonstrate tissue-specific recruitment of HSCs to the injured microvasculature. For instance, recruitment of HSCs in ischemically injured liver is dependent on the integrin sub-unit CD49d, while recruitment of HSCs in ischemically injured gut is dependent on the integrin sub-unit CD18. Additionally, a role for the non-integrin glycoprotein CD44 appears critical in mediating HSC recruitment to injured kidney. Since these adhesion molecules are essential for stem-endothelial cell interactions, modification of their surface expression, affinity for endothelial counterligands or avidity (clustering) may facilitate or impede recruitment of HSCs into specific tissues.

In addition to direct manipulation of adhesion molecules, chemokine pre-treatment strategies have promise in enhancing HSC recruitment to injured tissues. HSC pre-treatment with chemokines such as CXCL12 (SDF-1α) or KC (murine functional IL-8 homologue) significantly enhances their recruitment into the microvasculature of the ischemically injured intestine. Pre-treatment of HSCs with either CXCL12 or the reactive oxygen species, hydrogen peroxide (H_2O_2), can increase cell adhesion in the ischemically injured intestine. Crucially, these factors are released into the local microenvironment following ischemic tissue injury. Pre-treatment strategies may enhance adhesion via a number of mechanisms, including enhanced integrin clustering. Indeed, we have demonstrated that our HSC pre-treatment strategies are able to enhance surface integrin clustering. For instance, H_2O_2 (100μM; 1hr) significantly increases surface clustering of integrins CD18 and CD49d without affecting HSC viability or function (still capable of differentiation into mature hematopoietic cells). Interestingly, pre-treatment strategies may also modify SC kinetics through non-adhesion molecule related mechanisms. For instance, we have data to show that CXCL12 pre-treatment increases HSC deformability, as demonstrated using a micropipette aspiration method. This has important clinical implications as non-specific entrapment is considered a major obstacle for systemic SC delivery. Non-specific entrapment may reduce the pool of circulating transplanted SCs available for recruitment.

An additional biological approach to enhancing SC recruitment involves utilising platelet-derived microparticles (PMPs). PMPs are the predominant subtype of microparticle found in peripheral blood, with numbers increased in patients with inflammatory disorders. PMPs can 'coat' neutrophils and increase leukocyte-endothelial interactions. Based on this phenomena, we demonstrated that coating HSCs with PMPs prior to infusion in mice enhanced their recruitment in chronically injured colitis colon. We have recently performed parallel intravital studies to investigate the kinetics of MSC homing in vivo. Preliminary studies suggest distribution of MSCs post-infusion is not increased in injured tissue compared to healthy controls – this differs from HSC data.
Our understanding of the molecular mechanisms underlying SC homing to sites of injury is increasing and allowing us to develop strategies that can modulate their adhesion. Our ongoing studies have demonstrated that enhancing HSC presence confers a greater anti-inflammatory effect within the local microcirculation. While it is easy to presume that enhanced SC recruitment may be beneficial in models of injury, we should be wary that an "over-recruitment" may have deleterious effects. Certainly, MSCs can behave pro-fibrotically and may worsen the local tissue milieu in conditions of injury. Whether enhancing local MSC presence proves beneficial or detrimental is currently being investigated.

Identification of resident c-kit expressing vascular endothelial stem cells on the adult blood vessel wall

S. Fang, J. Wei, N. Pentinmikko, H. Leinonen and P. Salven

Department of Pathology, Haartman Institute,University of Helsinki, Helsinki, Finland

Angiogenesis is essential many physiological and pathological events, for instance in wound repair and tumor progression. The origin of newly-formed blood vessel endothelial cells in adults is not known. Here we identified and isolated c-kit+ vascular endothelial stem cells (VESCs) by the phenotype lin-CD31+CD105+Sca1+CD117+, a small subpopulation residing on the vessel wall. A single transplanted VESC is able to generate functional blood vessels in connection with the host circulation and maintain a long-term self-renewal capacity in vivo. Further, we showed that a genetic deficit in endothelial c-kit expression remarkably decreases total colony-forming VESCs, indicating a functional role of c-kit in VESCs. A deficit in c-kit expression also resulted in impaired angiogenesis and growth retardation in tumor. Thus, VESCs would provide a novel cellular target to inhibit pathological angiogenesis in cancer therapies. Isolated VESCs could also be utilized in therapies to restore tissue vascularization in many diseases.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Pericytes for cardiovascular repair: a roadmap towards first-in-man trial

P. Madeddu

Bristol Royal Infirmary, Bristol, UK

Pericytes for cardiovascular repair: a roadmap towards first-in-man trial Paolo Madeddu, Prof. MD FAHA University of Bristol Recent studies have highlighted the regenerative potential of progenitor cells from human vasculature. This presentation will address the protocol for isolation, expansion and preclinical testing of human pericytes from saphenous veins of elderly cardiovascular patients in view of a first in human clinical trial. We have so far isolated pericytes from more than 70 venous samples and characterized variability of preparations and we are now introducing clinical grade reagents, including the use of immunomagnetic beads for separation of antigenically defined cells and serum free media.
We have also obtained initial epigenetic hits that predict preclinical therapeutic activity and indicate safety of the cell product.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Perivascular adipose tissue as a determinant of organ perfusion

E.C. Eringa

Department of Physiology, Institute for Cardiovascular Research, VU University Medical Centre, Amsterdam, Netherlands

Accumulation of ectopic fat is strongly related to risk of type 2 diabetes and cardiovascular disease. One of the most important fat depots in this context is perivascular adipose tissue (PVAT), which is situated around most blood vessels with a diameter >100 microns. In organs such as adipose tissue, muscles and the heart, PVAT associates with resistance arteries, suggesting a role in (dys)regulation of perfusion of these tissues. As perfusion is a determinant of local glucose metabolism, PVAT control of tissue perfusion may also contribute to regulation of insulin sensitivity. In recent years, PVAT around resistance arteries has been found to induce vasodilatation by direct relaxing effects on smooth muscle and enhancement of vasodilatation induced by insulin and acetylcholine. These vasodilator properties of PVAT are mediated by a variety of bioactive substances (adipokines) such as adiponectin and inflammatory mediators. In human and experimental obesity, hypertension and Western diet exposure, impaired vasodilator properties of PVAT have been observed. This is triggered by infiltration of inflammatory cells such as macrophages in PVAT and, in muscle, associates with reduced perfusion. In conclusion, vasoregulation in resistance arteries by PVAT contributes to regulation of local perfusion and metabolism, and impairment of this function of PVAT may be a novel mechanism underlying insulin resistance and target organ damage in type 2 diabetes.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Adipokine signaling and angiogenesis

A. Bouloumie

INSERM U1048, Toulouse, France and University Paul Sabatier, Toulouse, France

The adipose tissue plays a major role in energy homeostasis as the main tissue of energy reserve but also as source of adipokines involved in the control of metabolic fluxes. Among them, many adipokines exhibit pro-angiogenic activities including leptin (1), the family of vascular endothelial growth factors, the angiopoietins, hepatocyte growth factor, angiopoietin like factor 4, apelin, visfatin, the families of fibroblast growth factors and of matrix metalloproteinases (2). Anti-angiogenic factors such as thrombospondins, Secreted Protein Acidic and Rich in Cysteine, osteopontin, resistin, the metalloproteases inhibitors and plasminogen activator inhibitor 1 are also produced by TA (2). The global angiogenic status of the human AT is modulated mainly by the adiposity degree and the AT location. Indeed, a global increase in AT angiogenic status is found with obesity. This effect might be related to the accumulation of immune-inflammatory cells within AT including macrophages shown to stimulate angiogenesis in AT (3) . Hypoxia, that may be consecutive to the increased size of adipocytes (or hypertrophy), is a condition that will increase the production of pro-angiogenic adipokines in AT (4). Distinct angiogenic statuses are described according to the fat mass location, visceral AT being considered more proangiogenic than subcutaneous fat mass (5). Angiogenesis within AT is a key event in the cellular homeostasis during fat mass development and most of the approaches to lower angiogenesis have been shown to interfere with AT growth and whole energy expenditure (6). This key mechanism may become pathological under too strong local angiogenic pressure leading to accelerated aging of endothelial cells (5) and ultimatively to endothelial cell dysfunction. Therefore the link involving adipokines in the communication between adipocytes and endothelial cells is of great interest to better understand the link between obesity and associated pathologies.

PVAT function in obesity: mechanisms and therapy

A. Heagerty

The University of Manchester, Manchester, UK

There is now clear evidence that adipocytes are engine rooms producing a large number of factors which can have profound influences upon adjacent tissues. In particular, perivascular fat can influence arterial tone and healthy adipocytes secrete a number of vasorelaxing molecules. Recent evidence has suggested that one of these playing a prominent role is adiponectin and the bioavailability of this adipokine is lost when subjects become obese and develop maturity on-set diabetes or the metabolic syndrome. Adiponectin appears to be released by the stimulation of beta-adrenor receptors located on adipocyte plasma membranes and its actions involve nitric oxide both in the endothelium and in the adipocyte itself. Crucial to the normal functioning of this pathway is the BKCa channel and knockout mice demonstrate no vasorelaxing activity of perivascular fat. In the obese state there is adipocyte hypertrophy and activation of recruited macrophages. Evidence suggests that without the macrophage there is no loss of perivascular vasodilator activity and our most recent data following up patients who have undergone bariatric surgery suggest that this intervention is associated with a loss of inflammation and the restoration of normal perivascular fat function.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Cardiac t-tubules as a specialised microdomain for trans-sarcolemmal Ca flux and its regulation in health and disease

C. Orchard, S. Bryant and A. James

School of Physiology and Pharmacology, University of Bristol, Bristol, UK

The transverse (t-) tubules of mammalian cardiac ventricular myocytes are invaginations of the surface membrane that form a complex network within the cell. The function of many of the key proteins involved in cardiac excitation-contraction coupling occurs predominantly at the t-tubules: acute detubulation results in an ~80% decrease of L-type Ca current (I_{Ca}), an ~65% decrease of Na-Ca exchange current (I_{NCX}), and complete loss of Ca extrusion via the sarcolemmal Ca ATPase (see Orchard *et al*., 2009 for review; Chase & Orchard, 2011). Thus the majority of trans-sarcolemmal Ca influx and efflux occurs across the t-tubule membrane, which ensures that both activation and relaxation occur rapidly throughout the cell.
Cell signalling is also different at the t-tubule and surface membranes: the β-adrenergic agonist isoprenaline causes greater stimulation of I_{Ca} at the t-tubules than at the surface mem-

brane, suggesting better coupling of the β -adrenergic pathway to I_{Ca} at the t-tubules (Brette *et al*., 2004), and recent work suggests that localisation of I_{Ca} and I_{NCX} to the t-tubules is due, in part, to localised stimulation of these currents at the t-tubules by basal activity of protein kinase A (PKA; Chase *et al*., 2010; Chase & Orchard, 2011). Since β_2 adrenoceptors occur predominantly in the t-tubules in normal ventricular myocytes (Nikolaev *et al*., 2010), it seems possible that tonic activity of the β_2 adrenergic pathway underlies this localisation.

To investigate further the mechanisms underlying this localisation, we have used a membrane-permeable peptide representing the scaffolding domain of Caveolin-3 (Cav-3; MacDougall *et al*., 2012). This peptide (C3SD) reduced basal I_{Ca} and inhibited the stimulatory effects of the β_2-adrenergic agonist zinterol on I_{Ca}. The PKA inhibitor H-89 also reduced basal I_{Ca}; however, the inhibitory effects of H-89 and C3SD on basal I_{Ca} were not summative, suggesting that they share a common pathway involving PKA. Thus Cav-3 appears to play an important role in facilitating stimulation of I_{Ca} by basal PKA activity and in response to β_2-adrenoceptor stimulation, consistent with the hypothesis that basal activity of the β_2-adrenergic pathway underlies stimulation of I_{Ca}, to which it is coupled via Cav-3.

T-tubules may also play an important role in pathological conditions. Changes in t-tubule morphology have been reported in both human heart failure (HF) and in animal models of HF, with t-tubule structure becoming disordered, with consequent changes in the synchrony of Ca release. Changes in cell signalling also occur: H-89 has a greater inhibitory effect on basal I_{Ca} in myocytes isolated 16 weeks after coronary artery ligation than in those from sham operated controls, suggesting greater stimulation by PKA, as shown previously. However, C3SD does not decrease I_{Ca} significantly in the ligation model (Bryant *et al*., 2013), suggesting that the coupling of PKA activity to I_{Ca} by Cav-3 described above is already disrupted. Although the role of the t-tubules in these changes is still being elucidated, it is interesting that HF is associated with redistribution of β_2 adrenoceptors from the t-tubules to the surface membrane, and a change from localised to diffuse cAMP signalling in response to β_2 adrenoceptor stimulation (Nikolaev *et al*., 2010), making it tempting to speculate that loss of Cav-3 coupling plays a role in these changes.

Thus the t-tubules appear to form a specialised domain for trans-sarcolemmal Ca flux and its regulation, and thereby play a key role in physiological and pathophysiological cell function.

Optical recording of action potential propagation in transverse-axial tubular system

L. Sacconi[1,3], C. Crocini[1], C. Ferrantini[2], R. Coppini[2], C. Tesi[2], E. Cerbai[2], C. Poggesi[2] and F.S. Pavone[1,3]

[1]European Laboratory for Non-Linear Spectroscopy, Sesto Fno, Italy, [2]University of Florence, Sesto F.no, Italy and [3]National Institute of Optics, Florence, Italy

T-tubules are invaginations of the plasma membrane that conduct the electrical depolarization to the cardiomyocyte core, allowing a fast and synchronous Ca2+ release. We have recently developed an ultrafast random access multi-photon (RAMP) microscope that, in combination with a customly synthesized voltage-sensitive dye (VSD), is used to simultaneously measure action potentials (APs) at multiple sites within the sarcolemma with submillisecond temporal and submicrometer spatial resolution in real time. We found that the tight electrical coupling between different sarcolemmal domains is guaranteed only within an intact tubular system. In fact, we found that AP propagation into the pathologically remodeled tubular system frequently fails and may be followed by local spontaneous electrical activity (Sacconi et al. PNAS 2012). To clarify the link between tubular abnormalities and Ca2+-dependent arrhythmias, we combine the advantage of RAMP microscope with a double staining approach to optically record tubular AP and, simultaneously, the corresponding local Ca2+ transient. Isolated rat cardiomyocytes were co-loaded with the VSD and a green calcium indicator. Although the calcium and voltage probes can be excited at the same wavelength, the large Stokes shift of the VSD emission allows us to use spectral unmixing to resolve the voltage and calcium responses. The capability of our technique in probing spatiotemporal relationship between Ca2+ and electrical activity was explored in a model of acute detubulation in which failure to conduct AP in disconnected t-tubules causes local delay of Ca2+ transient rise.

SA128

Plasticity of cardiomyocyte t-tubules

O.M. Sejersted[1,2] and W.E. Louch[2,1]

[1]Univ of Oslo, Oslo, Norway and [2]Oslo University Hospital Ullevaal, Oslo, Norway

T-tubules are extensive tubular invaginations of the sarcolemma mostly located at the Z-line in cardiomyocytes. With membrane staining the t-tubules are seen to form a regular striation pattern with a sarcomere distance between the trans-

verse lines. However, the tubules are highly interconnected and wrap around the myofibrils. Here they come in close contact with the junctional part of the sarcoplasmic reticulum (SR) to form dyads where calcium induced calcium release occurs. In these specialized regions, L-type calcium channels and Na,Ca-exchangers in the t-tubule membrane, and ryanodine receptors of the SR are closely clustered. Hence efficient transmission of the action potential in the t-tubular system will provide a rapid calcium release that is synchronized throughout the cardiac cell with a short lag of a few ms (1). In failing hearts the t-tubules become disorganized and some longitudinal tubules start to appear. This reshaping of the t-tubular system contributes to dyssynchronous calcium release because a larger fraction of ryanodine receptors will be outside the dyads and calcium will have to diffuse a longer distance to activate them (1, 2). Thus, time to peak of the calcium transient becomes longer, and contraction slower. However, t-tubule disorganization can only explain part of the dyssynchrony. In failing hearts, the basic calcium release "quantum" – the spark – is altered. About 20% of sparks have a markedly slower rise time and some are quite prolonged. This variability in spark kinetics contributes to dyssynchrony of the calcium transient (3). The reason for this variability seems to be that in some dyads the ryanodine receptors become rearranged. Dyssynchrony can be partly offset by increased SR calcium content and/or increased ryanodine receptor sensitivity to calcium (2). Prolongation of the action potential in failing hearts could also contribute to dyssynchronous calcium release, but this effect seems to be offset by increased sensitivity of the ryanodine receptors (4). If the SR function is dramatically decreased by removing the calcium-pump (SERCA2) in a conditional, cardiac specific knock-out mouse model, calcium for contraction is provided across the sarcolemma (5). In these hearts t-tubules proliferate and grow longitudinally in the cell. Dyads are formed at the A-band midway between the Z-lines (6). Interestingly, in these new dyads L-type calcium channels seem to be absent, whereas Na,Ca-exchangers are found opposite the ryanodine receptors. Thus, we believe that calcium entry via Na,Ca-exchange can trigger calcium release, indicating that the growth of new longitudinal T-tubules is compensatory. Thus, existing data show that T-tubules are highly plastic structures that can grow, shrink or become disorganized in the adult cardiac cells. This has important functional consequences for the formation of dyads and the efficiency and synchrony of calcium release throughout the cell.

Functional significance of atrial t-tubules: effects of heart failure

K. Dibb, J. Clarke, D. Eisner and A. Trafford

University of Manchester, Manchester, UK

T-tubules are deep invaginations of the cellular surface membrane containing a host of ion channels known to be important in excitation contraction coupling in the heart. While an important functional role for ventricular t-tubules has been well defined it has been generally assumed that the atria lacks these important structures. More recently our lab and others have demonstrated the existence of t-tubules in the atria of a number of large mammalian species including human. In cells where t-tubules are absent (small mammalian atrial myocytes) triggered release of Ca^{2+}, responsible for initiating cellular contraction, occurs only at the cell periphery. The presence of atrial t-tubules is associated with triggered Ca^{2+} release in the cell interior.

Ventricular t-tubules are decreased in heart failure, playing an important role in the pathophysiology of the disease. Using a sheep rapid paced model of heart failure (instrumented under anaesthesia with 1-4% isoflurane and analgesia provided by 0.25mg/kg meloxicam) we have shown atrial t-tubules to be virtually absent at the point of heart failure. Loss of atrial t-tubules in heart failure is associated with a reduction in the L-type Ca^{2+} current, the loss of triggered Ca^{2+} release in the cell interior and, significantly, a decrease in Ca^{2+} transient amplitude. It is therefore important to understand if t-tubules can be restored to the failing atria in order to restore function.

Following termination of rapid pacing sheep were allowed to recover from heart failure. Recovery was associated with the restoration of atrial t-tubules although these structures were extremely disordered. Preliminary data however suggests despite this disorder recovery of t-tubules may restore functional properties to the atria. Thus atrial t-tubules are not only important in normal excitation contraction coupling but also play a significant role in the pathophysiology of disease.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA130

Towards understanding the mechanism of T-tubule remodeling in cardiac disease

L. Song

Department of Internal Medicine, University of Iowa, Iowa City, IA, USA

The highly organized transverse (T)-tubule network is critical for rapid electric excitation and synchronous triggering of sarcoplasmic reticulum (SR) Ca2+ release, and, therefore, coordinated and efficient excitation-contraction coupling function in working ventricular myocytes. Because of the critical roles played by T-tubules, T-tubule architecture has recently become an area of considerable research interest in the cardiovascular field. Early studies from us and others have shown that the regularly arrayed T-tubule system undergoes disruptive remodeling, leading to aberrant intracellular Ca2+ release and compromised myocyte contractility, in failing myocytes from animal models and human patients. Recently, using in situ

confocal imaging technique, we showed that in a pressure overload rat cardiomyopathy model the remodeling of T-tubules starts much earlier in the disease spectrum, even prior to echocardiographically-detectable left ventricular (LV) systolic dysfunction. The T-tubule system in the LV undergoes progressive deterioration from compensated hypertrophy through early heart failure to advanced heart failure. Moreover, the integrity of T-tubule system highly correlates with cardiac ejection fraction of diseased hearts, indicating T-tubule integrity is a crucial determinant of cardiac function, and that maladaptive T-tubule remodeling is a causal event that drives the transition from compensated hypertrophy to heart failure. In more recent work, we have dissected the molecular mechanisms underlying T-tubule remodeling in heart disease, in particular the importance of junctophilin-2 (JP2), a structural protein spanning T-tubules and the SR membrane. JP2 is severely downregulated in multiple heart failure models as well as in failing human hearts. Furthermore, loss of JP expression correlates with the extent of T-tubule damage. In cultured myocytes, knockdown of JP2 using lentivirus containing a JP2 shRNA caused T-tubule disorganization. Transgenic expression of a JP2 shRNA in mice induced T-tubule structural damage, dyssynchronous and blunted Ca2+ release, and acute heart failure. These data provide compelling evidence that JP2 is a key mediator of myocyte T-tubule remodeling in cardiac disease.

Development of CO_2 chemoceptive respiratory circuits in the mouse embryo: Insights into congenital central hypoventilation syndrome?

G. Fortin

Neurobiology & Development, CNRS, Institut de Neurobiologie Alfred Fessard, Gif sur Yvette, France

We breathe roughly half a billion times in a lifetime, generally in an effortless and even unconscious manner owing to activity of a respiratory central pattern generator (CPG) located in the hindbrain. The respiratory CPG relies on the coupling of two prominent rhythmogenic sites located in the medulla, the pre-Bötzinger Complex (preBötC) and the retrotrapezoid nucleus/para-Facial Respiratory Group (RTN). Working in the mouse embryo, we have identified the emergence of embryonic versions of these two oscillators using developmental genetics tools, electrophysiological and optical recordings. We have recently defined molecular and functional signatures for cells composing each oscillator. The talk will focus on the embryonic version of the RTN, an Egr2- (also known as Krox20-) derived, Lbx1-/Atoh1- and Phox2b-expressing group of cells located at the ventral surface of the brainstem below the facial motor nucleus.

Mutations in the neuron type-specific homeogene *Phox2b* are causative for central congenital hypoventilation syndrome (CCHS). Introducing one of the most common human mutations (*Phox2b*^{27Ala}) in mouse leads to a CCHS-like respiratory syndrome, including apneas, arythmia, and unresponsiveness to a hypercapnic challenge —and neonatal death. This mutation preserves many *Phox2b*-positive neural structures, but destroys the retrotrapezoid nucleus (RTN). Similarly, Atoh1 null mutants feature a disrupted RTN and die at birth. Electrophysiological studies have implicated the RTN in central CO2 sensitivity and perinatal entrainment of the preBötC and downstream inspiratory outputs. We have confirmed this at embryonic stages using an optogenetic approach and patterned light photostimulation targeting RTN neurons. Altogether, these data point to the RTN as a major culprit in CCHS pathogenesis. However, we also found that spatially limited expression of the *Phox2b*^{27Ala} allele can be compatible with life, while nevertheless destroying the RTN and abolishing the perinatal hypercapnic response. Thus, the central chemoreflex is dispensable for neonatal life and defects in *Phox2b*-expressing neurons outside the RTN contribute to the full CCHS-like syndrome in mouse.

Do the carotid bodies modulate heart rate variability and baroreflex control of blood pressure in humans?

E.A. Wehrwein[1,2], J.L. Taylor[2], A. Basu[3], T. Curry[2], R. Basu[3] and M.J. Joyner[2]

[1]Physiology, Michigan State University, East Lansing, MI, USA, [2]Anesthesia Reserach, Mayo Clinic, Rochester, MN, USA and [3]Endocrine Reserach, Mayo Clinic, Rochester, MN, USA

Hypoglycemia impacts baroreflex control of blood pressure and cardio-vagal tone. The carotid bodies are sensitive to low glucose and mediate hypoglycemic counterregulation. Peripheral chemoreceptors in the carotid body also regulate respiration, sympathetic outflow, and blood pressure by serving as multi-modal physiological sensors. We hypothesized that desensitization of the carotid bodies by hyperoxia during hypoglycemia would blunt baroreflex control of blood pressure and cardio-vagal tone. Ten young healthy adults were exposed to normoxia [PaO2 122 ± 3 mmHg] or hyperoxia [PaO2 424 ± 39] (to blunt cellular activation of the carotid body glomus cells) during a hyperinsulinemic-hypoglycemic clamp (2 mU/kg FFM/min; 3.33 mmol/L). Two 180 min hyperinsulinemic-hypoglycemic clamps were performed on each subject one week apart, randomized to either normoxia or hyperoxia ($p<0.05$). Blood pressure was monitored continuously via a brachial arterial catheter. Cardio-vagal tone was assessed via the high fre-

quency (HF) component of heart rate variability from 5 min periods of 5-lead ECG recording under baseline (euglycemia) and hypoglycemia. Mean blood pressure during hypoglycemia was significantly lower with hyperoxia than with normoxia (delta reduction from baseline: -5.4 ± 3.4 mmHg normoxia vs. -13.8 ± 1.9 mmHg hyperoxia, $p<0.05$). The typical baroreflex-mediated rise in heart rate and sympathetic activity with lower blood pressure did not occur when the carotid bodies were silenced. Area under the curve values (expressed as % normoxia response) for catecholamines during hypoglycemia were significantly suppressed by hyperoxia (norepinephrine -50.7 ± 5.2%, epinephrine -62.6 ± 3.3%, $p<0.05$ vs normoxia). HF values decreased significantly from baseline during hypoglycemia, however this reduction was attenuated under hyperoxia (Normoxia: -69% vs. Hyperoxia: -41%, $p=0.04$). Heart rate increased significantly during hypoglycemia (Normoxia: 59.7 bpm ± 2.4 vs. 71.9 ± 4.0; Hyperoxia: 60.6 bpm ± 1.9 vs. 68.5 ± 3, $p<0.001$), however, this increase was not different between normoxia and hyperoxia despite differences in cardio-vagal tone, heart rate variability, and blood pressure. These data indicate that the carotid body chemoreceptors may be partially responsible for the reduction in cardio-vagal tone associated with hypoglycemia, and they provide evidence for a role of the carotid body chemoreceptors in parasympathetic tone to the heart and sympathetic mediation of the baroreflex. Together, these data support the idea that the carotid bodies play a role in heart rate variability and baroreflex control of blood pressure in humans.

Central chemoreceptors in developing heart failure

A. Gourine[1] and S. Kasparov[2]

[1]University College London, London, UK and [2]University of Bristol, Bristol, UK

Heart failure may lead to hypoperfusion and hypooxygenation of tissues and this is often exacerbated by central and obstructive sleep apnoeas associated with recurrent episodes of systemic hypoxia and hypercapnia/hypocapnia. Astrocytes residing in the rostral ventrolateral medulla oblongata (RVLM) may function as specialized brain chemoreceptors. They sense PCO2/pH changes and via release of ATP impart these changes on neurones of the ventral respiratory column triggering adaptive increases in the respiratory activity. We used in vitro and in vivo models to determine whether selective activation of RVLM astrocytes leads to the release of ATP, and via release of ATP increases the activity of sympathoexcitatory (pre-sympathetic) RVLM neurones. We also explored whether ATP actions in the RVLM contribute to maladaptive and detrimental sympathoexcitation in heart failure.

It was found that optogenetic activation of RVLM astrocytes transduced to express light-sensitive channelrhodopsin-2 activates sympathoexcitatory RVLM neurones in ATP-dependent manner. In anaesthetized rats in vivo, optogenetic stimulation of RVLM astrocytes increases sympathetic renal nerve activity, arterial blood pressure and heart rate. To interfere with ATP-mediated signalling by promoting extracellular breakdown of ATP, we developed a lentiviral vector to express a potent ectonucleotidase - transmembrane prostatic acid phosphatase (TMPAP) on the cellular membranes. In rats with myocardial infarction-induced heart failure, expression of TMPAP bilaterally in the RVLM led to a lower plasma noradrenaline concentration, maintained left ventricular (LV) end diastolic pressure, attenuated decline in dP/dT(max) and shifted the LV pressure-volume relationship curve to the left.

These results demonstrate that activated RVLM astrocytes are capable of increasing the activity of the brainstem sympathoexcitatory neuronal circuits while facilitated breakdown of ATP in the RVLM reduces sympathetic tone, attenuates the progression of LV remodelling and heart failure secondary to myocardial infarction. Our data provide the first experimental evidence suggesting that altered glial activity leading to higher level of "ambient" ATP in the brainstem might be responsible for the increases in sympathetic tone and by doing so contribute to the development and progression of heart disease associated with increased activity of the sympathetic nervous system.

The research in our laboratories referred to in this abstract was funded by The Wellcome Trust and the British Heart Foundation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Significance of the carotid body in insulin resistance and hypertension

S.V. Conde[1], M.J. Ribeiro[1], J.F. Sacramento[1], C. Gonzalez[2], A. Obeso[2] and G.P. Maria[1]

[1]Pharmacology, CEDOC, Faculdade Ciencias Médicas, Universidade NOVA, Lisboa, Portugal and [2]Bioquimica, Biologia Molecular e Fisiologia, Universidad de Valladolid, Facultad de Medicina. Instituto de Biología y Genética Molecular, CSIC. Ciber de Enfermedades Respiratorias, CIBERES, Instituto de Salud Carlos III, Valladolid, Spain

Increased sympathetic activity is a well-known pathophysiological mechanism in insulin resistance (IR) and hypertension (HT). The carotid bodies (CBs) are arterial chemoreceptors being PO2, PCO2/pH sensors-efectors which upon a decrease in PO2 or a PCO2/[H+] increase, release neurotransmitters that regulate the firing rate in the sensory fibres of the carotid sinus nerve (CSN). CSN activity is integrated in the brain stem to induce a fan of respiratory reflexes aimed, primarily, to normalize the altered blood gases via hyperventilation (Gonzalez et al.1994) and to regulate blood pressure and cardiac performance via sympathetic nervous system activation (Marshall 1994). The CB directly activates the adrenals via increased sympathetic drive and also increases sympathetic vasoconstrictor outflow to muscle, splanchnic, and renal beds (Marshall 1994; Cao & Morrison 2001). Recently, the CB was proposed to be a glucose sensor (Pardal & López-Barneo 2002) and implicated in energy homeostasis control (Koyama et al. 2000). However, to date no studies have anticipated its role in the development of IR. The aim of this work was to investigate the role of the CB in the pathogenesis of IR and HT.

Experiments were performed in Wistar rats (200–420 g) of both sexes, aged 3 months. Two diet-induced IR and HT animal models were used: the rat submitted to a high-fat (HF) diet, a model that combines obesity, IR and HT and the rat submitted to a high-sucrose (HSu) diet, a lean model of combined IR and HT. To test the hypothesis that CB activity is increased in IR and HT animal models we compared HF and HSu with control group. To evaluate the contribution of CB to the gen-

esis of IR and HT, bilateral resection of CSN was performed 5 days prior to submitting the animals to standard or hypercaloric diets. These procedures were performed in aseptic conditions under ketamine (30mg/kg)/xylazine (4mg/kg) anaesthesia and brupenorphine (10microg/kg) analgesia. Additionally, rats fed with standard diet were used to investigate if insulin triggers CB activation. All measurements were performed with animals under sodium pentobarbital (60 mg/kg i.p.) anaesthesia.

We demonstrated that CB activity was increased in diet-induced animal models of IR and HT. CB-mediated basal ventilation and ventilation in response to ischemic hypoxia were increased in the pathological models tested, as well as the CB chemoreceptor cell function - assessed both as hypoxia induced-release of dopamine and as tyrosine hydroxilase expression. We have also observed that CSN bilateral resection totally prevented diet-induced IR and HT, as well as increased fasting glicemia, fasting insulinemia, free fatty acids and systemic sympathoadrenal overactivity. Moreover, we showed that insulin triggers CB, highlighting a new role for hyperinsulinemia as a stimulus for CB-overactivation. We demonstrated that insulin receptors are present in the CB and that its phosphorylation increases in response to insulin. Additionally, we showed that insulin was capable of initiating a neurosecretory response measured as the increase in intracellular Ca2+ and the release of the neurotransmitters, ATP and dopamine, that is transduced into an increase in ventilation.

We propose that CB is implicated in the pathogenesis of metabolic and hemodynamic disturbances through sympathoadrenal overactivation and may represent a novel therapeutic target in these diseases.

Noradrenergic neurons and control of the central and peripheral chemoreflex

L. Gargaglioni

Animal Morphology and Physiology, Sao Paulo State University, Jaboticabal, Sao Paulo, Brazil

The noradrenergic cell groups provide neural inputs to almost all brain areas including the respiratory network. Developmental dysfunctions in these neurons are linked to pathological conditions such as Rett syndrome and Sudden Infant Death, which can impair the control of the cardio-respiratory system and coordination of the sleep-waking cycle. We have been evaluating the involvement of A5 and A6 (locus coeruleus - LC) cell groups in the cardiorespiratory response to central (7-10% CO_2 in air) and peripheral (7-10% O_2) chemoreflex stimulation. A reduction of approximately 80% of noradrenergic (NA) neurons of LC is associated with a large decrease in the respiratory response to CO_2 of approximately 64%, indicating that this nucleus exerts a profound effect on the CO_2-drive to breathe, but no effect is observed during low O_2 conditions (Biancardi et al., 2008; 2010). These data suggests the specific role of LC NA neurons in the ventilatory response to high CO_2 rather than to hypoxia. Many neurotransmitters/neuromodulators have been demonstrated to be involved in the modulation of the LC response, such as serotonin, orexin, glutamate, ATP and also the GAP junctions (Gargaglioni et al., 2010). As to cardiovascular response, chemical lesion of the LC with 6-hydroxydopamine (6-OHDA) does not affect mean arterial pressure and heart rate during normocapnia and hypercapnia, indicating that noradrenergic LC neurons are unlikely to play a significant role in the control blood pressure and heart rate. However, lesion of LC using substance P-saporin conjugate (SP-SAP), that kills NK-1 immunoreactive (NK1R-ir) neurons, increase the heart rate during hypercapnia, suggesting that NK1R-ir neurons in the LC, probably the GABAergic ones, may modulate heart rate during CO2 exposure, since Glutamic Acid Decarboxylase immunoreactivity decreases after SP-SAP lesion (de Carvalho et al., 2010). Regarding A5 region, the role of this NA group in central and peripheral chemoreflex is strongly dependent on the state of the animal, anesthetized or unanesthetized. In unanesthetized animals, A5 noradrenergic neurons exert an excitatory modulation on the ventilatory response to hypoxia but do not affect cardiorespiratory control during CO_2 exposure. However, in urethane-anesthetized animals, A5 noradrenergic neurons contribute to the sympathoexcitation and the increase in phrenic nerve activity produced by raising the end-expiratory CO_2 (Taxini et al., 2011). In addition, under anesthesia, these noradrenergic neurons are not involved in autonomic regulation elicited by peripheral chemoreflex activation.

Perception and the expectation of reward

K. Krug

Physiology, Anatomy & Genetics, Oxford University, Oxford, UK

The effect of reward is thought to be pervasive. It affects our motor actions and our sensory judgements. We have investigated the influence of reward on perceptual decision-making at multiple levels in humans and macaque monkeys. We set up a behavioural paradigm that could be employed with both species. The perceptual decision-making task involved reporting the direction of rotation of a structure-from-motion cylinder made up of two transparent sheets of random dots. Cylinder rotation could be disambiguated by applying binocular disparity to separate the front and back surface of the cylinder. This allowed us to present a range of stimuli in each experiment, including the case of an ambiguous cylinder stimulus whose direction of rotation could either be perceived as clockwise or counterclockwise on a given trial.

Two Rhesus macaques were each implanted with a headpost, eye coils and a recording chamber under general anaesthesia (7-8 mg/kg/hr alfaxalone/alfadolone acetate i.v. or 1-3% isoflurane gas, to effect) (Dodd et al 2001; Read and Cumming 2003). They were trained to report the direction of rotation of the cylinder by making a saccade to one of two choice targets. They received a fluid reward for a correct decision; for ambiguous stimuli they received a fluid reward on 50% of randomly selected trials. The amount of fluid they received increased in a predictable fashion after two and then four consecutive, correct choices. We used electrical microstimulation in extra-striate visual area V5/MT to distinguish the separate roles of sensory neural signals arriving in V5/MT (and therefore not influenced by microstimulation) from the combined neuronal signals downstream of V5/MT (which are influenced by microstimulation). Electrical stimulation of a cluster of neurons selective for a particular direction of cylinder rotation biased visual perception. Psychometric functions for discrimination of cylinder rotation were consistently shifted, with the animal making more choice in the preferred direction of cylinder rotation at the stimulation site. Importantly, the size of this electrical microstimulation effect on the psychometric function was different when the reward available at the end of a trial was large or small (Wilcoxon signed-rank test: $p<0.001$, $n = 48$ stimulation sites). This result suggests that reward affected sensory signals separately from the artificially introduced electrical signal rather than simply acting upon the combined neural signal downstream of V5/MT. When we fitted psychometric functions with a simplified drift diffusion model, the best fitting model required a significant change in drift rate as well as a change in bound, indicating that reward affects both the early sensory stages and the later decision-related stages of cortical processing.

Further evidence for this conclusion comes from a study with six human participants carrying out the same perceptual task under different reward conditions, in which the reward is points converted into money at the end of the experiment. Preceding each trial, human participants were cued to indicate whether both choices were rewarded equally or one higher than the other (8 versus 1 point). Only correct responses were rewarded; for ambiguous stimuli, half the trials were rewarded at random. Feedback of points scored was given at the end of every trial and the cumulative score was given at regular intervals during the experiment. Under these conditions, participants showed a consistent behavioural response bias towards more highly rewarded choices for the same cylinder stimulus. Analysis with a drift diffusion model again implicated changes in drift rate to account for the effect of reward, the stimulus parameter that represents the strength of the sensory evidence being integrated to the decision (Model fit t-test comparison across individuals, $p<0.05$). Human magnetoencephalography (MEG) recordings with a beamformer analysis showed that after the cue onset but prior to stimulus onset, there was activation for biased reward conditions over balanced reward in both V5/MT at around 475 msec and dorsolateral prefrontal cortex (dPFC) at 590 msec. When the cylinder stimulus on a given trial had a direction of rotation that was highly not lowly rewarded, we found cortical activation in the precuneus in visual cortex at 85 msec after stimulus onset followed by dPFC at 125 msec and other prefrontal areas during stimulus presentation.

These results, obtained with humans and monkeys, show that signals in visual cortex are affected by the reward available on a given trial. This suggests that in perceptual decision tasks, one mechanism by which reward could influence behaviour might be through biasing of signals in the visual processing areas of the brain.

Reconciling rapid neuronal and perceptual adaptation to motion

N. Price

Physiology, Monash University, Clayton, VIC, Australia

Prolonged exposure to an "adapting" visual stimulus improves our ability to detect and discriminate subsequently viewed "test" stimuli that have similar properties to the adaptor. These changes in perceptual sensitivity are often accompanied by reductions in the firing rates and shifts in the tuning curves of sensory neurons. Adaptation may help reduce the redundancy of neural codes, improving how the brain represents prevailing stimulus conditions. It allows a dynamic trade-off between the range of stimuli that can be represented by a neuron's firing rate and the minimum detectable difference between stimuli. The best functional example of adaptation comes from the retina, where ganglion cells can encode luminance over many orders of magnitude, but adaptation can shift the sensitivity of individual neurons to optimally represent the prevailing conditions. However, the links between neuronal and perceptual adaptation remain poorly understood for even basic stimulus properties such as colour, shape and motion. In particular, while adaptation is well characterised at the level of single neurons, few studies have examined how adaptation affects the responses of populations of neurons. This is important, because perception depends on both the firing rates, and structure of response correlations, across a population of neurons. To better understand how adaptation affects sensory encoding by neuronal populations, we implanted multi-electrode arrays in a range of visual cortical areas in anaesthetised mar-

mosets. The marmoset is an ideal model for array recordings because its smooth cortical surface ensures most brain areas are readily accessible with electrode arrays. We recorded visual-evoked spiking activity at up to 128 sites in V1, V2 and the dorso-medial area (DM). We used two main stimulus sets: first, direction tuning was characterised in an unadapted case using moving gratings; second, direction tuning was characterised after adaptation to 1-2 seconds of sustained exposure to motion in a single direction. In addition, we characterised the receptive field locations of all neurons.

At the single neuron level, the effects of adaptation depended on the cortical area. In all areas, neuronal gain, or the peak firing rate evoked by a test stimulus, was reduced following adaptation, regardless of the relationship between a neuron's preferred direction and the adaptation direction. In V1/V2, adaptation produced "repulsive" changes in tuning, such that the post-adaptation preferred direction was shifted away from the adaptation direction. Surprisingly, in DM, no consistent changes in direction tuning were observed following adaptation.

To characterise effects at the population level, we determined spike-count correlations (rSC). For each pair of neurons, rSC is the Pearson correlation between the spike counts evoked by multiple repetitions of an identical stimulus. Before adaptation, rSC between a pair of neurons was highest when the neurons had similar preferred directions and had the greatest level of overlap in their receptive fields. This is expected from previous work, and reflects the larger proportion of inputs shared between neurons with similar sensitivity. After adaptation, average rSC across the population remained constant, but the structure of correlations changed in a tuning-dependent manner. rSC decreased for neurons with similar direction preferences, leading to a smaller range of correlations across the population.

We argue that this decorrelation is a way of optimising sensitivity to the prevailing stimulus conditions, consistent with Barlow's original hypothesis that adaptation decorrelates the activity of a neuronal population to reduce redundancy. However, the tuning-dependence of the decorrelation suggests that adaptation is only able to affect a limited range of inputs to a population of neurons, notably those that are shared locally, between neurons with similar preferences, rather than those that are globally shared across all neurons in an area. The implications of this tuning-dependent correlation for perception are captured in a population decoding model.

Perception and action in three-dimensional vision

P. Janssen

KU Leuven, Leuven, Belgium

The visual analysis of three-dimensional (3D) shape relies on a network of cortical areas in the primate ventral (Janssen et al., 2000) and dorsal (Srivastava et al., 2009) visual stream. Previous studies have emphasized that distinct neural representations of disparity-defined 3D shape exist in the inferior temporal cortex (ITC), the posterior parietal cortex (area AIP) and even in the premotor cortex (area F5a). Here I will review a series of studies that relate the neural selectivity in these cortical areas to perception and action. Using a combination of single-cell recordings, fMRI, electrical microstimulation and reversible inactivation in behaving macaque monkeys (Maccaca mulatta), I will argue that the extensive processing of 3D shape subserves different behavioral goals. Specifically, neural activity in ITC correlates with perceptual choice (Verhoef et al., 2010), and microstimulation in ITC predictably alters the categorization of convex and concave 3D shapes and accelerates the time to decision (Verhoef et al., 2012). In contrast, 3D-shape selective neurons in the parietal (AIP) and premotor cortex (F5a) are also active during grasping of 3D objects (Theys et al., 2012; Theys et al., 2013), and reversible inactivation of clusters of 3D-shape selective neurons in AIP produces a strong grasping deficit but no perceptual deficit. Furthermore microstimulation of AIP produces weak effects on 3D-shape categorization and generally prolongs the decision time (Verhoef et al., in preparation). Finally, microstimulation of 3D-shape selective AIP neurons during fMRI reveals the functional connectivity of these neurons: consistent with the known anatomical connectivity, AIP microstimulation selectively activates F5a in the ventral premotor cortex and area CIP in the posterior Intraparietal sulcus. Thus a combination of research techniques and behavioral tasks can clarify how 3D shape processing is related to both perception and action.

The neural mechanisms involved in finding objects and switching between targets

N.C. Rust

Psychology, University of Pennsylvania, Philadelphia, PA, USA

Finding specific objects and switching between targets requires the flexible integration of visual and task-specific information. To investigate how the brain solves a target-switching task, we recorded neural responses in perirhinal cortex (PRH) and its primary input, inferotemporal cortex (IT) as subjects performed a task that required finding different targets in different blocks of trials. Our results suggest that visual and

target information are initially combined within or before IT in a "tangled" or nonlinearly separable manner, followed by "untangling" computations in PRH that reformat this information such that it is more accessible via a linear read-out. These computations culminate in a subpopulation of "bingo neurons" in PRH that fire whenever a target is currently in view, across changes in target identity.

SA140

Progression of target-to-gaze command coding in superior colliculus and frontal eye fields during head unrestrained gaze shifts

D. Crawford

Psychology, York University, Toronto, ON, Canada and Centre for Vision Research, York University, Toronto, ON, Canada

The most fundamental question in sensorimotor physiology is, 'how do neurons transform sensory information into motor commands'? Take for example the case of visuospatial transformations for gaze control (where gaze is the product of both eye and head movement). The input is clearly target location relative to the retina, and the output is clearly muscular commands for eye rotation relative to the head and head rotation relative to the body, but the intermediate transformations are difficult to pinpoint. Distinguishing between different intermediate codes is made difficult by their relative similarity (e.g., target angle, gaze angle, eye and head rotation) relative to the variability of behavior and neural noise.

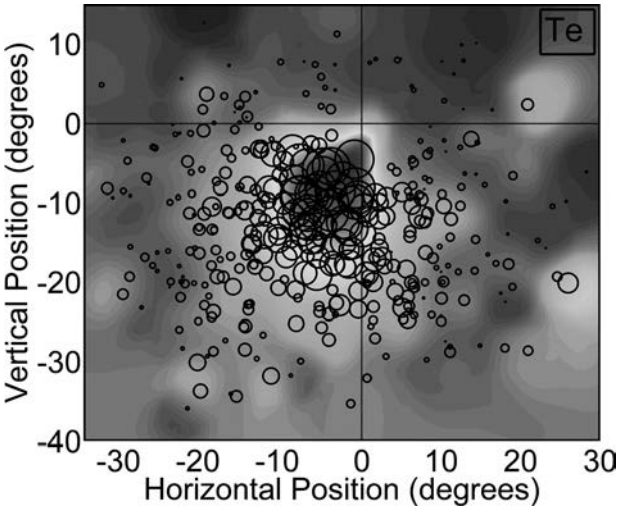
Our solution to this has been to develop a method that allows one to map visual and motor response fields (RFs) relative to different possible representations (i.e., target position, gaze, eye, and head displacement or final position) in various frames of reference, i.e., relative to eye, head, or space (see figures). This allows a number of 'model fits', whereby we determine the best fit to be the one that produces the least residuals of raw neural data to the model (Keith et al. 2009). In our first application of this method (DeSouza et al. 2011), we found that the bursts of neural activity in the superior colliculus (SC) during head unrestrained gaze shifts made directly to briefly flashed visual targets dominantly code the location of the target relative to initial eye orientation, rather than the detailed parameters of the gaze, eye, or head movement.

Here, we performed similar experiments on the SC and frontal eye fields (FEF) in two rhesus monkeys, the key structures involved in outputting early visual signals and gaze commands to the brainstem. To isolate the question of visual-motor transformation we used a delayed memory task where animals were required to continue fixating briefly for a variable time between seeing the target and shifting their gaze. Target positions were varied throughout the RF of each neuron tested, and initial gaze fixations were varied (along with natural animal-selected variations of initial eye and head position) to allow us to separate the spatial frame of the neural code. Three-dimensional (3-D) eye and head orientations were recorded so that we could account for small torsional 'twists' of the eye around the line of site, and for correct mathematical analysis.

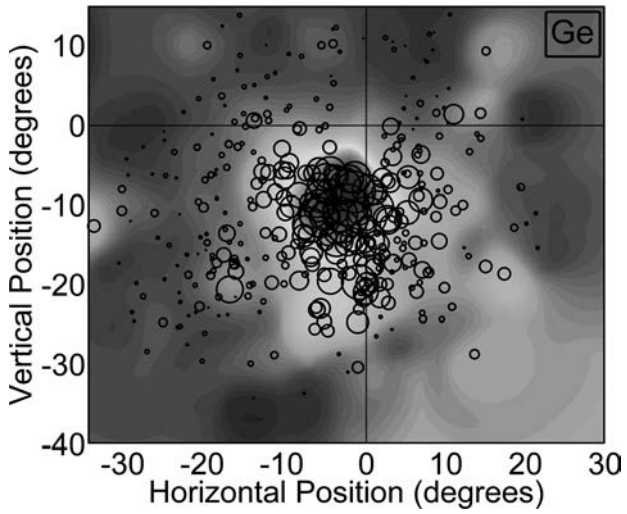
For the SC (Sadeh et al. 2012), we found that the visual response (to the appearance of the target) of all of the neurons we tested gave the best fit to target relative to initial eye orientation (Te). Perhaps surprisingly, in 'visuomotor' neurons that showed both a visual response and a motor response during the gaze shift, the motor response also coded for Te. It was only in cells that did not have any visual response that the motor response fit best to a motor parameter: final gaze position relative to initial eye orientation (Ge; or the mathematically similar gaze displacement model Gd). Note that these gaze models were spatially separable from target models because we allowed monkeys to be somewhat 'sloppy' with their final gaze positions around each target.

For the FEF (Sajad et al. 2012), a similar picture emerged, especially in the visual responses, but in FEF cells all motor responses preferred Ge over Te (see Figures). Since many FEF cells showed both visual responses (fitting Te) and motor responses (fitting Ge), we also looked at the memory delay activity between them, and found a gradual progression of activity fitting best along the continuum between Te and Ge, leading up to the gaze shift. In none of our 71 SC neurons or 64 FEF neurons did we observe a response that significantly preferred an individuated motor effector (eye or head) or a non-eye-centered frame of reference.

These results show that –although the SC and FEF show subtle differences in our paradigm— they both employ similar eye-centered codes for vision and gaze. This finding suggests that such codes are only worked out a later stage of the visuomotor transformation- most likely in the brainstem. More interestingly, we have shown that both of these structures are involved with intrinsic transformations of target-based spatial codes to gaze motor codes, not only between different cell and response types, but within some cortical neurons, across time for different aspects of the task. Since these are fundamental properties of neural coding, one expects similar principles to apply to the early stages of other sensorimotor transformations.



Visual response field (RF) for a frontal eye field (FEF) neuron. Circle size indicates number of action potentials evoked by (80-180ms after) target presentation during individual trials. The grey scale indicates a non-parametric fit to these individual trials. Data are plotted in the coordinates that gave the lowest residuals between individual trials and the fit: angle of target position relative to initial 3-D eye orientation (Te).



Motor response field (RF) for the same frontal eye field (FEF) neuron. Circle size indicates number of action potentials occurring during the gaze shift for individual trials. The grey scale indicates a non-parametric fit to these individual trials. Data are plotted in the coordinates that gave the lowest residuals between individual trials and the fit: angle of final gaze position relative to initial 3-D eye orientation (Ge).

Nutrient sensing of Group C GPCRs

H. Bräuner-Osborne

Department of Drug Design and Pharmacology, University of Copenhagen, Copenhagen, Denmark

G protein-coupled receptors (GPCRs) are divided into Group A, B and C receptors based on phylogenetics. The majority of Group C GPCRs consist of a large extracellular 'Venus Flytrap' domain and Cystein-rich domain followed by a 7-transmembrane domain. The 'Venus Flytrap' domain is homologous to periplasmic binding proteins which act as amino acid and nutrient transporters in bacteria. Likewise, human Group C GPCRs have been shown to binds amino acids, cations and sugars and thus potentially act as nutrient sensors in mammals [1]. We have paid particular interest to the Group C receptor entitled GPRC6A, which will be the focus of the present talk. In 2004 we reported the cloning and tissue expression of the GPRC6A receptor [2]. Using a variety of pharmacological assays at the human, mouse and rat receptor orthologs expressed in Xenopus laevis oocytes and mammalian cell lines, we have shown that the receptor is Gq coupled and promiscuously activated by L-amino acids of which the basic L-amino acids L-Arg, L-Lys and L-ornithine are the most potent [3-4]. In addition, we have shown that the receptor is co-activated by divalent cations such as calcium [4-5]. Unfortunately, these endogenous agonists also act on a range of other targets, which decreases their use as pharmacological tool compounds. Novel tools are thus warranted to study the physiological function of the receptor including its potential role as nutrien sensor. To this end, we recently reported the first GPRC6A selective negative allosteric modulators (NAMs). The NAMs, based on so-called privileged structures containing a 2-phenyl-indole scaffold, were inferred from family A receptors using chemogenomics [6]. Another strategy has been to develop a GPRC6A knockout mouse where exon 6 containing the entire 7TM domain was removed. We have shown that the GPRC6A knockout mice had wild-type-like growth rate [7] body composition and glucose metabolism [8] when fed a regular chow diet. However, when the mice are fed a 60% high fat diet the knockout mice become more obese than their wild-type littermates and show impaired glucose metabolism [9]. Given that the GPRC6A receptor is expressed in the islets of Langerhans and that L-amino acids such as L-Arg are known to increase insulin secretion, we hypothesized that the impaired glucose metabolism could be caused by decreased L-amino acid insulin secretion. However, both ex vivo experiments on isolated islets and in vivo experiments demonstrate that the GPRC6A knockout mice demonstrate wild-type-like L-Arg mediate insulin release [8]. Collectively, these studies of our GPRC6A knockout mice indicate a role as nutrient sensor. However, further studies are needed to delineate the precise mechanisms of the observed phenotype.

Dietary programming of hypothalamic nutrient-sensing

N. Balthasar, M. Wherlock, H. Weir, A. Simpson and L. Dearden

School of Physiology and Pharmacology, University of Bristol, Bristol, UK

How do dynamically modulated neuronal transcriptomes underpin long-term adaptive changes that lead to positive processes, such as learning, or negative adaptations, like failure to sense metabolic state? This is a core question in neurobiology and ultimately CNS-mediated disease and my lab is using hypothalamic nutrient-sensing as a model to investigate the programmes supporting such neuronal plasticity.

Hypothalamic nutrient-sensing is critical for maintenance of appropriate body weight and glucose homeostasis. However, in clinical situations such as obesity and type 2 diabetes, but also recurrent hypoglycemia in type 1 diabetes, hypothalamic nutrient-sensing fails and adjustment of metabolic balance is lost. In addition to a continued rise in obesity and diabetes in an adult population, early life events are major determinants of obesity and diabetes risk with in utero exposure being of particular importance. With an increasing number of obese,

diabetic mothers, maternal programming of offspring metabolic homeostasis adds momentum to the 'obesity epidemic'. Our recent data investigate the neuroadaptive mechanisms underpinning neuronal responses to metabolic state. Indeed, many neuroadaptative responses are downstream of the induction of transcription factors and subsequent regulation of gene expression, which can have long-lasting effects on neuronal function. We have recently described a mechanism linking hypothalamic glucose-sensing with CRE-gene transcription via activation of a CREB co-activator and linked the subsequently induced transcriptome to the regulation of food intake. In addition, we demonstrate that maternal diet has significant effects on offspring hypothalamic transcriptome regulation and subsequently metabolic balance.
By combining the use of neuronal subpopulation-specific genetically modified mouse models with genome-wide transcriptomics and epigenomics approaches we are in the process of identifying mechanisms in environmental- and disease-mediated modifications of neuronal transcriptomes causing neuronal dysfunction.

Brain lipid sensing and nervous system control of energy balance

B.E. Levin

Neurology Service (127C), VA Medical Center, East Orange, NJ, USA

Energy homeostasis is regulated by a constant dialogue between metabolic and hormonal sensors in the periphery and the brain. Long chain fatty acids (LCFA) provide an important metabolic substrate that is sensed by specialized receptors and transporters located on metabolic sensing neurons that are widely distributed throughout the brain. These neurons alter their activity in response to a variety of other metabolic substrates and hormones. The LCFA receptor/transporter CD36 regulates LCFA sensing in more than half of the ventromedial hypothalamic (VMH) metabolic sensing neurons. Depletion of rat VMH CD36 alters body weight, food intake, carcass fat deposition, insulin sensitivity and linear growth depending upon the strain and age of rat used. But neuronal FA sensing is also markedly influenced by astrocyte-produced ketone bodies, especially in the face of high fat diet intake. This ketone production overrides the CD36-mediated FA sensing pathway and thereby alters food intake. Thus, neuronal FA sensing plays an important role in regulating energy homeostasis and is markedly influenced by dietary fat content.

Neural circuitry organizing behavioral responses to nutrient and electrolyte availability

G.L. Yosten

Pharmacological and Physiological Science, Saint Louis University, Saint Louis, MO, USA

Although the brain is capable of sensing a variety of nutrient signals, it must integrate those signals and generate an appropriate behavioral response. The Central Melanocortin System, composed of proopiomelanocortin (POMC)/alpha-MSH-producing neurons originating in the arcuate nucleus of the hypothalamus or the nucleus of the solitary tract, is perfectly positioned to integrate nutritional signals of both peripheral and central origin. Several neural systems have been implicated as downstream effectors of melanocortin actions; however, the organization and order of activation of those systems is only now becoming understood. Using pharmacological approaches in whole animal models, we have confirmed the association of the Central Melanocortin System with downstream activation of central corticotropin releasing hormone (CRH) receptors and the central oxytocin system. Furthermore, we have delineated the organization of this essential circuit, in that activation of CRH receptors occurs after stimulation of POMC neurons, which in turn leads to the activation of the central oxytocin system. Interestingly, although this circuit appears to be important for the regulation of feeding behavior, an alternative and as yet unknown circuit underlies the cardiovascular actions of the central melanocortin system. These findings may have important implications for the pathogenesis of obesity and its associated complications, including obesity-associated diabetes and hypertension.

SA145

Physiological biased signaling by the actions of Ca^{2+}_o or L-amino acids on the calcium-sensing receptor

A.D. Conigrave

University of Sydney, Sydney, NSW, Australia

The calcium-sensing receptor (CaSR) is a nutrient-sensing receptor that mediates feedback regulation of systemic calcium homeostasis in fetal and postnatal life, and also plays key roles in cell fate determination (survival, proliferation and differentiation) acting to support complex development programs for diverse organs including the CNS and lung (1). In this respect the receptor provides a 'switch' function that arises firstly from its expression in the presence of activating concentrations of Ca^{2+} and other nutrients, and secondly from local or systemic modulation of nutrient levels.
The CaSR's more general role in nutrient sensing arises from its membership of the taste receptor sub-group of GPCR class C. This it senses not only Ca^{2+} and Mg2+ ions but also L-amino acids (review: (2)) by which it plays roles in coordinating gastrointestinal responses to ingested dietary protein e.g., via

stimulating the release of enteric hormones including gastrin, cholecystokinin, GLP, GIP and PYY.

To achieve these diverse roles the CaSR exhibits ligand-directed (biased) signaling by which certain but not all ligands are restricted in their access to specific signaling pathways. The most striking comparison is between Ca^{2+} and L-Phe. Ca^{2+} activates all known pathways downstream of the receptor and its interactions with $G_{q/11}$, $G_{i/o}$ and $G_{12/13}$. L-Phe, on the other hand, activates a restricted set of signaling pathways downstream of $G_{q/11}$ and $G_{i/o}$ that appear to limit its actions primarily to the acute control of peptide hormone secretion.

The mechanisms that underlie these physiologically important restrictions on L-amino acid-dependent signaling are starting emerge and appear to include not only the adoption of ligand-specific receptor conformations but also posttranslational modifications such as PKC-dependent phosphorylation of CaSR residue T888.

The physiological significance of amino acid dependent signaling is being revealed in transgenic mice in which the CaSR's sensing functions for L-amino acids and Ca^{2+}_o have been dissociated.

The growth of academic physiology in Britain, 1860-1930

S. Jacyna

Centre for the History of Medicine, UCL, London, UK

This paper gives an account of the development of physiology as an academic discipline in Great Britain between the mid-nineteenth century and the early decades of the twentieth century. It pays particular attention to the movement of key individuals from Scotland to the new London University (subsequently renamed University College London) in the early part of the period. It then considers how individuals trained at UCL went on to found major schools of physiology in such other centres as Cambridge, Oxford and Edinburgh.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA147

Early physiology in Birmingham, c.1870-1930

J. Reinarz

University of Birmingham, Birmingham, UK

This paper emerges from a Wellcome-funded, comparative history of five English provincial medical schools between c.1825 and 1939. Among other things, it considers the establishment of the first provincial schools in England, the evolution of the curriculum, as well as the emergence of something that more closely resembles modern medical science. In many ways, the new scientific method in medicine was epitomised by physiology; this paper will therefore examine the rise of physiology and the emergence of provincial research schools of physiology. Given the local setting of this conference, this paper will explore the emergence of academic physiology (c.1870) in Birmingham and its development over approximately half a century. Among other things, it will discuss the first instructors, who were usually clinicians, which goes some way towards explaining the practical nature of the earliest classes. It also follows the development of physiology instruction, including the appointment of full-time professors and research laboratories. While it has been suggested that provincial schools often led those in the metropolis in their willingness to embrace courses such as physiology, they also had considerable difficulties first establishing programmes that would satisfy the demands of existing regulatory bodies.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The prevention and the treatment of frostbite in the early twentieth century

L.J. Howarth

Population, Socities and Humanities, University of Birmingham, Birmingham, UK and School of Medicine, University of Birmingham, Birmingham, UK

'Those who approached the fires, sufficiently near, to warm frozen feet and hands, were attacked by gangrene…these fatal occurrences mutilating the majority of our soldiers, threw them into the power of the enemy'. These words, spoken by Baron Larrey the chief surgeon to the French army in the Napoleonic wars, sound as horrific now as they did exactly 200 years ago. The soldiers expected warmth to heal their frostbitten sores; yet, it hastened their injuries to an irreversible gangrenous state. It is with Larrey the history of modern frostbite management and pathophysiology commenced. The history of frostbite has been briefly covered, but never in great depth or encompassing both previous military and exploration (polar and high-altitude) experiences together. This presentation offers a more general history of the prevention and the treatment of frostbite in the twentieth century. It covers the British experiences of frostbite from exposure in cold, hostile territories of the exploration campaigns and military operations. Discussed will be frostbite in the polar explorations (1910 - 1917), military frostbite (1914 – 1918) and finally Everest expeditions (1921 – 1938). Although different experiences, demonstrated is a progression in our understanding of frostbite and its management.

I would like to thank Dr. Jonathan Reinarz, the University of Birmingham Population, Societies and Humanities team, Dr. Vanessa Heggi and Dr. John Holden for their much valued time in helping me complete this research.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The Silver Hut Expedition: A seminal research expedition into high altitude medicine

R. Rabbitts

Yeovil District Hospital, Yeovil, UK and University of Birmingham, Birmingham, UK

The Himalayan Scientific and Mountaineering Expedition of 1960/61 remains one of the most ambitious and successful high altitude expeditions ever undertaken. Innovatively thought up by Sir Hilary and Dr Pugh, both well known figures in the field of high altitude research, it comprised of a team of physiologists who themselves would winter over at extreme altitude, a concept borrowed from the Trans-Antarctic Expeditions [1]. Significantly, this was the first attempt to look at the long term physiology behind acclimatisation and the effects of extreme altitude on the human body [2]. After spending the winter at extreme altitude the team, joined by some fresh members, would move to Mt. Makalu for an attempt on the summit. The attempt on Mt. Makalu allowed the scientists to see whether 'super-acclimatization' was possible. Observations conclusively showed that the wintering party were not at any advantage, apart from very initially [3]. The Silver Hut succeeded in removing variables commonly encountered on previous mountaineering expeditions to extreme altitude.

One of the physiologists; Dr James Milledge has been generous enough to share his personal recollections of the expedition in detailed personal interview which allows a more humane and practical side when discussing the expedition, highlighting the role he played within the expedition. Milledge was responsible for several experiments during the expedition. He looked at ventilation and showed that even after three months of living at 5800m, the primary respiratory drive was still caused by hypoxia [4]. Two important changes in the control of ventilation were confirmed. Firstly, there was an increase in carbon dioxide sensitivity, which took three to five weeks to develop. Importantly, Milledge showed that there was no further increase in carbon dioxide sensitivity after the initial month, this had not been demonstrated before [5]. The second change was a significant reduction in the threshold response to carbon dioxide [6]. Additionally, it had been previously been proposed that the hypoxic sensitivity would decrease when ascending to high altitudes. For the first time, it was shown that there was no change in hypoxic sensitivity when ascending to high altitude [7].

The expedition was extraordinarily successful and the scientific return was extensive. There were many publications emanating from the expedition, twenty of the thirty six articles were published in per reviewed journals. These results portray just what an enormous undertaking the expedition really was. It not only required immense organisation of every aspect of the expedition by the leaders, Pugh and Hillary, but also relied on the dedicated team of physiologists willing to partake in both performing the investigations and also being the subjects for the other team members' experiments. It was by far the most ambitious high altitude research expedition of its time. Remarkably, the legacy of the Silver Hut expedition is still stimulating further research today. The 2007 Caudwell Xtreme Everest expedition can trace its routes back to the Silver Hut and AMREE expeditions. It is significant that none of the scientific return has been disproven, and only a few findings superseded, much is still very relevant in present research.

SA150

Historical aspects of the physiology of high altitude

J.B. West

Medicine-Physiology, University of California, San Diego, La Jolla, CA, USA

The centenary of the Anglo-American high altitude expedition to Pikes Peak in 1911 provides an opportunity to look at the development of high altitude physiology before and since then. A watershed event was the publication of *La Pression Barométrique* by Paul Bert in Paris in 1878. This clearly implicated the low PO_2 in the air as the critical variable. A few years later the first high altitude research laboratory was erected on Mont Blanc at an altitude of 4350 m. Shortly thereafter Angelo Mosso from Turin arranged for the Capanna Margherita to be placed at an altitude of 4559 m on the Monte Rosa. This was the site of extensive physiological studies carried out by a burgeoning international high altitude physiology community. This included Nathan Zuntz from Berlin who organized an international expedition to the Alta Vista Hut, altitude 3350 m, on Tenerife, Canary Islands. The Pikes Peak expedition led by J. S. Haldane from Oxford and Y. Henderson from Yale had a classical design with measurements first at sea level, then on the summit, altitude 4300 m, for five weeks, and then back at sea level. Extensive studies of cardiorespiratory physiology were carried out which laid the basis of much of what we know today. More recently the first measurements of human physiology on the summit of Mt. Everest, altitude 8848 m, were made in 1981, a simulated ascent of Everest in a low-pressure chamber took place in 1985, and very recently arterial blood samples were taken near the summit. A dramatic advance has been the discovery of a genetic change in Tibetans with extensive implications for the oxygen transport system. High altitude physiology is one of the most colorful and fast moving areas of environmental physiology.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA151

OCTs: quintessential multidrug transporters

S.H. Wright

Physiology, University of Arizona, Tucson, AZ, USA

The kidney and liver secrete a diverse array of positively charged organic molecules, including many widely prescribed drugs. Although one characteristic of the suite of transporters that mediate this process is their (necessary) multiselectivity, it includes the potential for unwanted drug-drug interactions (DDIs) at the point of secretion, interactions that can influence a drug's clinical or toxicological profile. In addition, interactions at the level of renal (and hepatic) drug transport can influence drug accumulation within these organs, with concomitant effects on drug toxicity. Thus, predicting the occurrence of DDIs is a major focus of work on OC transport.

The cellular model of OC secretion by renal proximal tubule (RPT) cells, hepatocytes, and other barrier epithelia involves the sequential activity of an OC 'entry step,' from blood to cell across the basolateral membrane (BLM), via an electrogenic organic cation transporter; followed by an apical 'exit step,' from cell to the adjacent fluid-filled compartment (e.g., renal tubular filtrate or bile), mediated by electroneutral OC/H^+ exchange. Whereas apical 'exit' appears to be dominated by one or more members of the MATE family of transporters (Multidrug And Toxin Extrusion; SLC2247), OC 'entry' is mediated by one or more members of the Organic Cation Transporter family (SLC22A). This presentation focuses on these OCTs, with particular emphasis on the following issues:

(i) Site of OCT expression. OCT1 in humans is primarily expressed in the sinusoidal membrane of hepatocytes (with some in apical membrane of RPT cells and BLM of enterocytes). In rodents, Oct1 is expressed in BLM of RPT cells, as well as in the liver. OCT2 in humans and rodents is primarily expressed in BLM of RPT cells. In contrast, OCT3 has a very broad tissue distribution.

(ii) Molecular/structural properties. The human OCTs (554-556 amino acids) have 12 transmembrane helices (TMHs) and a protein fold that includes N- and C-terminal halves of 6 TMHs each, separated by a large water-filled cleft (the substrate translocation pathway) with an extensive, putative binding surface. An extracellular loop between TMHs 1 and 2 influences OCT-OCT interaction, including formation of functional multimers.

(iii) Energetics and kinetics. Although OCTs support electroneutral OC/OC exchange, the prominent physiological mode of operation is electrogenic uniport. Consequently, the inside negative membrane potential of RPT cells and hepatocytes is the principal driving force for OC^+ entry. Transport follows Michaelis-Menten kinetics with apparent K_m values that range from sub-μM to well above 1 mM. Substrates with low affinity frequently display comparatively large maximal rates, resulting in transport efficiencies ('V_{max}/K_m') that permit high flux even for 'low affinity' substrates.

(iv) Selectivity. The OCTs typically transport molecules that share little in common structurally except cationic charge, modest hydrophobicity, and one or more hydrogen donor/acceptor sites. Although the several pharmacophores developed to define the structural determinants of ligand interaction with OCT1 and OCT2 generally include these features, their 3D locations differ, perhaps reflecting use of structurally distinct substrates as the marker of OCT transport activity, i.e., a consequence of 'substrate-dependent' ligand interactions. Consistent with this possibility, the kinetics of ligand interaction (of both substrates and inhibitors) include competitive, noncompetitive and mixed-type mechanisms. Taken with current views of OCT structure (see above), it is likely that ligand binding to OCTs involves a large surface with multiple interaction sites.

(v) Regulation. The long cytoplasmic loop between TMHs 6 and 7 of all three OCTs contains multiple consensus phosphorylation sites potentially available for acute modulation of transport activity. Consistent with this observation, OCT1 and OCT2 respond to kinase activation (e.g., PKA and PKC), although there are substantial species differences in the resulting effect on transport. Sex steroids exert substantial influence on long-term expression of OCT2.

(vi) Impact on drug clearance. Elimination of Oct1 and Oct2 in mice eliminates TEA secretion, and decreases its accumulation in kidney and liver, supporting the view that OCTs mediate the entry step in OC secretion. The common (~15%) OCT2 polymorphism, A270S, alters metformin transport and has been correlated with changes in metformin PD and PK. However, whereas elimination of Oct1/2 decreases metformin clearance and tissue accumulation in mice (as expected), metformin PD effects were not diminished, complicating the link between OCT activity and drug PD.

It is clear that OCTs play a central role in drug clearance. But the field still falls short of the goal of predicting clinically relevant DDIs and the influence of genetic variation on OCT activity.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA152

Cellular processing of organic cation transporters (OCT)

B. Hirsch[1], S. Brast[1], A. Grabner[1], C. Albiker[1], E. Schlatter[1], L. Florin[2] and G. Ciarimboli[1]

[1]Department of Internal Medicine D, University Hospital Münster, Münster, Germany and [2]Institut für Medizinische Mikrobiologie und Hygiene, Johannes Gutenberg-Universität, Mainz, Germany

OCT are membrane proteins involved in the transport of endogenous (e.g. the biogenic amines dopamine and histamine) and of exogenous organic cations. OCT are highly expressed in excretory organs (kidney, liver) and also in the brain. For this reason, OCT have a crucial importance in modulating cerebral and renal dopaminergic activity and dopamine clearance from the blood. OCT determine also the efficacy and toxicities of drugs such as biguanides, platin derivatives, and tyrosine kinase inhibitors. OCT have been assigned to the SLC22A family. This family can be divided into various subgroups according to substrates and transport mechanisms. Three OCT subtypes (OCT1, OCT2, and OCT3) with specific organ distribution have been identified. In this work, we focused on human OCT2 (hOCT2), the renal subtype of OCT. Since one of the factors determining transporter function and regulation is the building of complexes with other proteins or with itself, we searched for interaction partners of OCT and investigated the functional role of such a complex.

For these investigations, a mating-based split-ubiquitin-yeast-two-hybrid system (mbSUS), fluorescence resonance energy transfer (FRET), Western blot analysis, crosslinking experiments, immunofluorescence, and uptake measurements of the fluorescent organic cation 4-4-(dimethylamino)styryl)-N-methylpyridinium (ASP) were applied to HEK293 cells stably

transfected with hOCT2 and partly also in freshly isolated human proximal tubules.
Since the quaternary structure of transmembrane proteins plays an essential role for their cellular trafficking and function, we investigated whether hOCT2 forms oligomeric complexes and if so which part of the transporter is involved in the oligomerization. The role of cysteines for oligomerization and trafficking to the plasma membranes was investigated in cysteine mutants of hOCT2. The mbSUS, FRET, and Western blot analysis shows that hOCT2 forms oligomers both in the HEK293 expression system and in native human kidneys. The cysteines of the large extracellular loop are important to enable correct folding, oligomeric assembly, and plasma membrane insertion of hOCT2. Mutations of the first and the last cysteines of the loop at positions 51 and 143 abolished oligomer formation. Thus, the cysteines of the extracellular loop are important for a correct trafficking to the plasma membrane and for oligomerization. Other than with itself, hOCT2 also interacts with the lysosomal associated protein transmembrane 4 alpha (LAPTM4A) as demonstrated by mbSUS, FRET, and pull-down experiments. LAPTM4A is an intracellular localized membrane protein associated to lysosomes and late endosomes. Functionally, overexpression of LAPTM4A significantly decreased ASP uptake in HEK293 cells stably transfected with hOCT2, suggesting a negative regulation of hOCT2 mediated transport. Furthermore, overexpression of LAPTM4A led to a significantly decreased hOCT2 plasma membrane expression in surface biotinylation experiments. Significant expression of LAPTM4A in human kidney was demonstrated by immunoblotting and immunofluorescence. The interaction hOCT2-LAPTM4A may give origin to a tandem structure, where organic cations, binding at the plasma membrane to hOCT2, are immediately directed by LAPTM4A to lysosomes, where they accumulate. Alternatively, the interaction leads to recruitment of OCT in an endocytotic compartment, where the complex hOCT2-LAPTM4A is digested.
Another direct interaction partner identified by mbSUS and confirmed by pull-down and also by FRET-FACS analysis is the tetraspanin CD63. Tetraspanin CD63 is a ubiquitously expressed protein of the endosomal system which also moves to the cell surface. Overexpression of CD63 significantly decreased organic cation transport in HEK293 cells stably transfected with hOCT2, while its down-regulation by siRNA stimulated it, suggesting a negative regulation of hOCT2 mediated transport by CD63. Furthermore, overexpression of CD63 significantly decreased hOCT2 plasma membrane localization in surface biotinylation experiments. Total interne reflection resonance experiments showed CD63-hOCT2 interaction in the plasma membrane but stronger in vesicular compartments. Expression and colocalization of CD63 with hOCT2 was demonstrated in human kidneys by immunohistochemistry. As functional consequences of CD63 knockout in mice we observed that hOCT2 lost its specific basolateral localization in the kidney, appearing to be widespread distributed in the cell with a significantly decreased transport rate. In conclusion, CD63 regulates in a physiologically relevant fashion the function of hOCT2. We speculate that CD63 influences its trafficking to/from the cell membrane and processing via the intracellular sorting machinery and that this processing depends on polarization behaviour of the cells.

An "Omics" view of Oats and Octs: the remote sensing and signaling hypothesis

S.K. Nigam

Pediatrics, Univ. of Calif., San Diego, La Jolla, CA, USA

Systems biology analyses of metabolomics and transcriptomics data from various SLC 22 transporter knockouts suggests a broad role in metabolism. Furthermore, classical signaling molecules (eg. prostaglandins, cyclic nucleotides, odorants and steroid conjugates) are among the best ligands for several original and more recently identified SLC22 family members. This, together with interesting tissue expression patterns in barrier epithelia under normal and perturbed conditions, as well as during organ development, has led to the hypothesis that these and other so-called drug transporters function as part of a "Remote Sensing and Signaling System" critical in the maintenance of local and systemic concentrations of rate-limiting metabolites and signaling molecules. This Remote Sensing and Signaling System involving SLC and ABC "drug" transporters may be important for inter-organ remote communication, functioning in parallel with other regulatory systems (eg. endocrine, growth factor, autonomic) as well communication between organisms (eg. gut microbiome-human).

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Exploring OCT physiological functions in the bronchial epithelium

M. Mukherjee[1], J. Lewis[1,2], L. Shemiss[1], A. Brown[1], I. Sayers[2], D.I. Pritchard[1] and C. Bosquillon[1]

[1]School of Pharmacy, University of Nottingham, Nottingham, UK and [2]School of Clinical Sciences, University of Nottingham, Nottingham, UK

The five main isoforms of the human Organic Cation Transporters (OCT), i.e., OCT1, OCT2 OCT3, OCTN1 and OCTN2 have been detected in the pulmonary tissue (1, 2) and there is published evidence these transporters impact on the absorption of inhaled drugs across the airway epithelium (2,3). In contrast, their physiological roles in the lungs have hardly been explored. It has been reported that OCT1 and OCT2 mediated the release of the non-neuronal acetylcholine from bronchial epithelial cells into the lung fluid (4) and that the OCT1-3 genes were dysregulated in the lungs of rodents following an acute ovalbumin challenge (5). However, the pathophysiological implications have not been investigated to date.
Since the airway epithelium is the primary protection barrier in the lungs, we initially assessed how environmental insults associated with chronic inflammatory pulmonary diseases affected OCT expression in bronchial epithelial cells. Layers of the human bronchial epithelial cell line Calu-3 cultured on permeable filters at an air-liquid interface for 21 days were used as a physiologically relevant in vitro model of the bronchial epithelium. Similarly to normal human bronchial epithelial cell layers, these expressed OCT1, OCT3, OCTN1 and OCTN2 while OCT2 could not be detected (6). Calu-3 layers were exposed to lipopolysaccharide (LPS), a common pro-inflammatory stim-

ulant, for 48h or to the aeroallergen house dust mite (HDM) for 8h twice over 48h. In parallel, they were also 'scrape' wounded using a pipette tip and allowed to recover for 48h. Changes in OCT gene and protein expression were measured by quantitative polymerase chain reaction (qPCR) or 'In-cell' Western, respectively. All three epithelial insults caused fold increases in the expression of OCT1, OCT3 and OCTN2 while OCTN1 was exclusively upregulated upon exposure to HDM at a concentration that compromised the integrity of the cell layer tight junctions (TJ). Interestingly, a non TJ disruptive concentration of the allergen only enhanced the expression of OCTN2.

Subsequently, the alveolar epithelial cell line A549 was used to evaluate the potential roles of OCT1 and OCTN2 in the mechanism of epithelial healing after injury as well as in airway protection against inflammation. The gene of the two transporters was successfully knocked down in the cell line using targeted siRNA. Knocked down layers grown on tissue culture plates were either scratched or challenged with LPS for 6h. Cell recovery after wounding was monitored by time lapse microscopy and by the Presto Blue® cell viability assay while the production of reactive oxygen species (ROS) upon LPS stimulation was measured using the dichlorofluorescein diacetate dye. In contrast to wild type cells, both OCT1 and OCTN2 knocked down layers failed to repair within 48h. In addition, low expression of the two transporters resulted in an increase in ROS formation following cell exposure to LPS.

Our data demonstrated that OCT expression in airway epithelial cells is affected by a pro-inflammatory stimulus, an allergen abuse and physical damage, with possible consequences in chronic inflammatory respiratory diseases. They also suggest OCT1 and OCTN2 participate in the repair of the airway epithelium after injury and might play a role in the control of oxidative stress during airway inflammation. The underlying mechanisms remain however to be investigated.

Organic cation transporter 2 controls response and vulnerability to stress

S. Gautron

UMRS952/UMR7224, Paris, France

In higher organisms, the response to stress plays an important role in optimizing the reactions and behavioral strategies in terms of perception, risk assessment and decision-making in the face of potential threats. However, the repeated solicitation of the biological systems underlying this response also imposes a negative burden on mental health by promoting mood-related disorders such as depression. The polyspecific organic cation transporters (OCTs) were shown previously to be sensitive to the hormone corticosterone in vitro in cultured cells, suggesting they might play a role in the physiological response to stress. In a recent study, we examined the implication of organic cation transporter 2 (OCT2) in the response to stress. We found that OCT2 is expressed in several stress-related circuits in the brain and along the hypothalamo-pituitary-adrenal (HPA) axis. Genetic deletion of OCT2 in mice strikingly enhanced the hormonal response to acute stress. As a consequence, OCT2–/– mice were potently more sensitive to the effects of chronic stress on depressive-like behaviors. The functional state of the GSK3β intracellular signaling pathway, highly responsive to acute and chronic stress, was altered in the hippocampus of OCT2–/– mice. In vivo pharmacology and Western blot experiments argue for increased serotonin tonus as a main mechanism for impaired Akt/GSK3 signaling in OCT2–/– mice brain. Our findings identify OCT2 as an important determinant of the response to stress in the brain, suggesting that in humans OCT2 mutations or blockade by diverse drugs may interfere with mood-related central functions and enhance vulnerability to repeated adverse events leading to depression.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA156

TRPC, Orai1 and STIM1 in physiological and pathological Ca2+ influx

S. Muallem

NIH, Bethesda, MD, USA

A critical component of the receptor-evoked Ca2+ signal is Ca2+ influx mediated by the TRPC and Orai channels and is regulated by the ER luminal Ca2+ sensor STIM1. Ca2+ influx is essential for all cell functions, yet excess Ca2+ influx is highly toxic and is involved in numerous cellular pathologies. A key question is how STIM1 interacts and open these channels. Most aspects of STIM1 interaction with the TRPC and Orai channels have been studied in model system, while the behavior of the native proteins is not known, in particular in polarized cells. We used model system and gene deletion in mice to study regulation of Orai and TRPC channels by STIM1. We identified several critical domains in STIM1 that are required for regulation of the channels. In particular, the STIM1 SOAR domain mediates interaction of STIM1 with both channel type. The newly discovered CTID domain downstream of SOAR regulates access of the inhibitor SARAF to SOAR. SOAR also mediates interaction of STIM1 with the C terminus of TRPC channels to present the basic lysine-rich domain of STIM1 to the TRPC channels to gate them. The localization of the native Orai1, TRPCs and STIM1 in polarized cells provide further clues as to the regulation and potential role of TRPC channels in cellular pathology. Finally, deletion of TRPC channels in mice markedly affect acinar cells receptor and store mediated Ca2+ influx and protects the cells from Ca2+-mediated toxicity brought about by cell stress.

Protective role of calmodulin in pancreatic toxicity

J. Gerasimenko

Cardiff School of Biosciences Cardiff University, Cardiff, UK

The most frequent causes of acute pancreatitis are either gallstones or heavy alcohol consumption. Recurrent episodes of acute pancreatitis often result in progression of the disease to chronic pancreatitis and increase the risk of pancreatic cancer. The pathogenesis of inflammation in acute and chronic pancreatitis is tightly linked to the induction of necrosis and apoptosis. There is currently no specific therapy for pancreatitis; however, latest findings allow hope for future progress. Single pancreatic acinar cells and clusters of two or three acinar cells were isolated from the mouse pancreas. The mice were humanely killed according to the UK Schedule 1 regulation of the Animal (Scientific Procedures) Act, 1986. Cells were loaded with calcium sensitive dye Fluo-5N AM followed by permeabilization using a short pulse of high intensity two-photon laser beam. BZiPAR was used to continuously measure the activity of trypsin by adding the substrate to the perfusion chamber after cell permeabilization. Measurements of fluorescence were performed using Leica multi-photon SP5 system.
Recently we have shown that the calcium sensor calmodulin provides a protective mechanism, regulating the sensitivity of the calcium release process. Activation of calmodulin using Ca2+-like peptide 3 (CALP-3) abolished the pathological calcium release and trypsinogen activation evoked by ethanol as well as its non-oxidative metabolite palmitoleic acid ethyl ester (POAEE) in intact and permeabilized cells. We have experimentally compared a number of ways to reduce calcium overload inflicted by known pancreatitis inducing factors (alcohol, fatty acid ethyl esters, bile acids, high concentration of cholecystokinin) including inhibition of calcium release, inhibition of calcium entry, potentiation of calcium recovery and activation of calcium regulation mechanisms. Our data suggest that activation of calcium regulation and inhibition of calcium entry (or possibly combination of both) reduces calcium overload as well as necrosis, bringing hope for new therapeutic approaches.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Pancreatic Stellate Cells (PSCs): a starring role in pancreatitis and pancreatic cancer

M. Apte

Pancreatic Research Group, University of New South Wales, Liverpool, NSW, Australia

While the morphology and function of most of the cells of the exocrine and endocrine pancreas have been well described over several centuries, one important cell type in the gland, the pancreatic stellate cell (PSC), was first described only as recently as 30 years ago. Furthermore, it was to be another 16 years before the biology of these cells could begin to be studied because it was only in 1998 that methods were developed to isolate and culture PSCs from rodent and human pancreas. PSCs are now known to be key players in pancreatic fibrosis, a predominant histological feature of two major diseases of the pancreas - chronic pancreatitis and pancreatic cancer.
In health, PSCs are in their quiescent phase and are characterised by abundant vitamin A storing lipid droplets in their cytoplasm. The cells are responsible for maintaining normal pancreatic architecture via regulation of the synthesis and degradation of extracellular matrix (ECM) proteins. Recently, PSCs have also been implicated in other functions as progenitor/stem cells, as immune cells and as intermediaries in exocrine pancreatic secretion in humans. During pancreatic injury, PSCs change to an activated, myofibroblast-like phenotype, characterised by loss of the vitamin A stores and the synthesis of excessive amounts of ECM proteins resulting in the fibrosis of chronic pancreatitis and pancreatic cancer. An ever increasing number of factors that stimulate and/or inhibit PSC activation via paracrine and autocrine pathways are being identified. Furthermore, the signalling pathways and second messengers mediating the effects of exogenous or endogenous factors on PSC function are being increasingly characterized. Importantly, it has now been clearly demonstrated, using both in vitro and in vivo approaches, that PSCs interact closely with pancreatic cancer cells to promote local tumour growth as well as distant metastasis. PSCs from primary tumours in the pancreas have also been shown to travel to distant metastatic sites where they likely facilitate the seeding and subsequent proliferation of cancer cells. In view of the central role of PSCs in both chronic pancreatitis and pancreatic cancer, current research is focussed on novel therapeutic strategies to inhibit/retard PSC activation and to interrupt their interaction with cancer cells so as alleviate chronic pancreatitis and/or inhibit tumour growth. The challenge that remains is to translate these pre-clinical developments into clinically applicable treatments for patients with chronic pancreatitis and pancreatic cancer.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The effects of pancreatitis-inducing factors on calcium signaling in pancreatic ductal cells

P. Hegyi[1], V. Venglovecz[1], P. Pallagi[1], J. Maléth[1], M.A. Gray[2] and Z. Rakonczay Jr.[1]

[1]First Department of Medicine, University of Szeged, Szeged, Hungary and [2]Institute for Cell & Molecular Biosciences, Newcastle University, Newcastle upon Tyne, UK

Excessive ethanol (EtOH) consumption and biliary tract diseases are the most common etiological factors of acute pancreatitis. In vivo pancreatitis animal models have revealed that not only acinar cells, but most probably the pancreatic ductal epithelial cells (PDEC) are also involved in the pathogenesis of acute pancreatitis (ref.1). One of the main aims of our workgroup is to understand the role of PDEC in acute pancreatitis. In recent years we have characterized the effects of different bile acids, ethanol, ethanol-metabolites and activated proteases on PDEC function.
Both EtOH and bile acids have dual effects on pancreatic ductal bicarbonate secretion. Low concentrations of these toxic factors stimulate, whereas high concentrations, inhibit the secretory process. Importantly, the stimulatory effects of both toxic factors are calcium dependent. EtOH and bile acids induce an oscillatory calcium elevation which can be blocked by BAPTA-AM, caffeine, xestospongin C and the phospholipase C

inhibitor U73122, but not by the lack of extracellular calcium (ref.2). Administration of high concentrations of EtOH, bile acids and fatty acids induce a sustained calcium elevation. This sustained calcium elevation is caused by (1) calcium release from the endoplasmic reticulum, via IP3 and ryanodine receptor activation;(2) by inhibiting the endoplasmic reticulum calcium ATPase and (3) by stimulating extracellular calcium influx. Blocking this sustained calcium elevation by BAPTA-AM prevents the inhibitory effects of EtOH and fatty acids, but not that caused by bile acids. The inactive protease trypsinogen has no effect on calcium, however, trypsin induces calcium elevation via activation of PAR2. Inhibiting this calcium elevation, either by trypsin inhibitor, a PAR antagonist or BAPTA-AM totally blocks the inhibitory effect of trypsin (ref.3).
These results indicate that pancreatitis-inducing factors strongly and differentially modulate intracellular calcium, which interferes with the secretory activity of PDEC. Understanding the calcium transporters/channels involved in these pathophysiological mechanisms may lead to more specific therapies for acute pancreatitis.

Calcium signaling and pancreatic stellate cell function

D.I. Yule

Pharmacology and Physiology, University of Rochester, Rochester, NY, USA

The exocrine pancreas is comprised of three prominent cell types. While the roles of the acinar and ductal cells in physiology and disease are reasonably well defined, a third cell type, the pancreatic stellate cell (PSC) is far less studied. PSC are present in a periacinar and periductal localization. In common with hepatic stellate cells they are characterized as retinol/lipid storing cells expressing a variety of intermediate filament proteins including desmin and glial fibrillary acid protein. Under physiological conditions, stellate cells appear to be quiescent and relatively little is known regarding their contribution to the normal function of the gland. However, in culture, PSC undergo a phenotypic transformation from a quiescent state to a myofibroblast-like phenotype. This is believed to parallel the induction of an activated state observed in chronic pancreatitis and pancreatic cancer. Activated PSCs are highly proliferative, migratory and secrete large amounts of extracellular matrix. These properties are thought to contribute to the pathogenesis of pancreatic disease. The goal of the present study was to define the role of changes in intracellular Calcium concentration ([Ca2+]i) in mouse PSC function. We have utilized a variety of techniques, including pharmacological agents and adenoviral constructs which buffer [Ca2+] and Inositol 1,4,5-trisphosphate in specific cellular compartments and used these approaches to probe the contribution of Ca2+ release and Ca2+ influx for PSC function. For example, data will be presented which suggests that Ca2+ signaling does not appear to play a major role in the activation of quiescent PSC. Nevertheless, following activation, an increase in [Ca2+] within the nucleus is required for proliferation. This appears to be dependent on Ca2+ release, because blockade of Ca2+ influx is without effect on growth. In contrast, migration of activated stellate cells is attenuated in the absence of Ca2+ influx. These data suggest that Ca2+ signaling plays multiple roles in PSC function and further that manipulation of this signal may be a promising future target for clinical intervention.

Altered excitability of dorsal horn neurons

J.A. Lopez-Garcia

Physiology, University of Alcala, Alcala de Henares, Madrid, Spain

The mechanisms underlying central sensitization following peripheral injury of inflammatory or neuropathic nature are the centre of an intense scientific debate. Potential mechanisms have been classified into 4 categories including synaptic mechanisms, membrane excitability changes, phenotypical changes and morphological reorganization (Sandkühler et al, 2000). We have studied changes in membrane excitability of deep dorsal horn neurones induced by peripheral inflammation. We expected to find enhanced membrane excitability in sensitized neurons.
Intraplantar injections of carrageenan produce clear signs of pain hypersensitivity in mice and rats. Spinal cords from these hyperalgesic animals maintained *in vitro* show significant signs of potentiated segmental reflexes which is interpreted as a sign of central sensitization (Hedo et al 1999). Therefore, we have used the mouse isolated spinal cord *in vitro* coupled to intracellular techniques to compare the excitability of neurons extracted from naïve and inflamed animals. Cords were always extracted under urethane anaesthesia (2 g/kg, i.p.) following approved protocols.
Neurons from treated animals showed large synaptic responses shortly after inflammation (1h) and developed further after a long term inflammation (20h). In contrast, these treated neurones showed biphasic changes in membrane excitability with an increase shortly after inflammation and a decrease in the longer term.
These observations lead to the conclusion that membrane excitability plays a complex role in central sensitization. Whereas an increased excitability may be a fast means to boost central sensitization, longer term decreases in excitability may represent a homeostatic correction of an abnormal state of synaptic activity.
This new framework opens a window for the study of particular ionic currents and specific ion channels in the dynamic shaping of cell excitability during sensitization. We have shown the contribution of transient and sustained potassium currents to this changing excitability (Rivera-Arconada & Lopez-Garcia 2010). Recently we have also investigated a potential role for

the mixed Ih current carried by HCN channels (Rivera-Arconada et al, 2013). Additional evidence from the laboratory suggests that the potassium M current may be involved in shaping excitability during sensitization. These experimental studies will be discussed within the presentation.

Mitochondrial dysfunction in chemotherapy-induced neuropathy

S. Flatters

Wolfson Centre for Age-Related Diseases, King's College London, London, UK

Painful peripheral neuropathy is the major dose-limiting side effect of several first-line, highly effective chemotherapeutic agents. Currently there is no effective therapy for the prevention or treatment of chemotherapy-induced painful peripheral neuropathies (CIPPN). Furthermore, several analgesics with established efficacy in other painful neuropathies have failed to show any efficacy in double-blind, placebo-controlled RCTs of patients with CIPPN. Therefore understanding the causal mechanisms for CIPPN is essential to enable analgesic development in this area of substantial unmet clinical need. Several reports using rodent models of CIPPN have indicated evidence for mitochondrial dysfunction and reactive oxygen species (ROS) to be contributory factors to this pain syndrome. Our research team at King's College London, is examining the contribution of mitochondrial function before, during and at the resolution of paclitaxel-induced painful peripheral neuropathy to correlate cellular mechanisms to whole animal behaviour. During this talk, I will discuss some of our latest data on ROS and mitochondrial function during paclitaxel-induced painful peripheral neuropathy.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA163

Microglia causing neuropathic pain after nerve injury

K. Inoue

Kyusyu University, Fukuoka, Japan

Neuropathic pain is a highly debilitating chronic pain that occurs after nerve injury and is resistant to currently available treatments. We reported that activated microglia overexpressed P2X4 receptors after nerve injury which release brain-derived neurotrophic factor (BDNF) evoking a collapse of their transmembrane anion gradient and the subsequent neuronal hyper-excitability (Nature, 2003 & 2005). Recently, we found that a single intrathecal administration of IFN-γ to normal animals produces a long-lasting tactile allodynic behavior and activation of microglia in the spinal cord. The expression of IFN-γ receptor mRNA in the spinal cord is localized predominantly in microglia. IFN-γ evoked P2X4 up-regulation through Lin-kinase activation in microglia. Furthermore, IFN-γ receptor-deficient mice (ifngr-/-) exhibited a striking reduction in nerve injury-induced tactile allodynia and activation of microglia. We also found that CCL2, ligands for CCR2, increased P2X4R expression in microglial surface fraction. These findings suggest that IFN-γ signaling through IFN-γR plays as a crucial trigger of microglia activation after nerve injury and the subsequent tactile allodynia through P2X4 stimulation, and that CCR2 signaling may increase the P2X4R expression on the surface membrane of microglia.

Microglia become activated by multiple types of damage in the nervous system, and play essential roles in neuronal pathologies. However, how microglia transform into reactive phenotypes is poorly understood. Then, we identified the transcription factor interferon-regulatory factor 8 (IRF8) as a critical regulator of reactive microglia. IRF8 expression was markedly upregulated in microglia, but not in neurons or astrocytes, after nerve injury. IRF8 overexpression in cultured microglia promoted the transcription of genes associated with reactive states; conversely, IRF8 deficiency prevented these gene expressions in the spinal cord following PNI. Furthermore, IRF8-deficient mice were resistant to neuropathic pain, and transferring IRF8-overexpressing microglia spinally to normal mice produced pain. Therefore, IRF8 may activate a program of gene expression that transforms microglia into a reactive phenotype.

SA164

BDNF-induced plasticity before and after SCI

S.M. Garraway

Psychology, Texas A & M University, College Station, TX, USA

For nearly two decades, much research has focused on brain-derived neurotrophic factor (BDNF), an important member of the neurotrophin family. Results from these studies show that BDNF exerts numerous modulatory actions within the central nervous system; actions ranging from cellular and molecular to behavioral. In the spinal cord, BDNF is identified as a critical mediator of central sensitization and spinal nociception that underlie the development of pain hypersensitivity. In addition to these actions, BDNF has also been implicated in beneficial effects such as promoting functional recovery following spinal cord injury (SCI). The existence of both adaptive and maladaptive spinal effects of BDNF has led us to propose that BDNF functions in a state dependent manner; that its specific actions are determined by whether or not a SCI exists.

To affirm this proposal, we conducted studies that utilized several experimental designs to investigate the effects of BDNF on spinal plasticity in naïve and spinal cord injured subjects. In the first set of studies, we used spinal cord slices in juvenile rats to examine the effect of exogenously administered BDNF on dorsal root-evoked synaptic currents in lamina II neurons. The results showed that in naïve subjects, BDNF produces a prolonged synaptic facilitation that requires post-synaptic NMDA receptors, protein kinase C and increases in intracellular calcium, indicating a pro-nociceptive role for BDNF. However, BDNF fails to induce facilitation of the evoked synaptic

responses in the injured spinal cord. The second set of experiments used a simple instrumental learning paradigm to assess the interaction between controllable shock and BDNF in adult rats with a complete spinal transection. Previous studies had shown that controllable shock to the hindlimb promotes adaptive plasticity and facilitates subsequent spinal learning through BDNF-dependent mechanisms (Gómez-Pinilla et al., 2007; Neuroscience 148:893-906). Supporting this, we demonstrated that controllable shock significantly increases the expression of BDNF and its receptor, TrkB, primarily in the spinal dorsal horn. Our third set of experiments assessed the relationship between spinal BDNF levels and the detrimental effects of intermittent nociceptive stimulation (~0.5Hz) in adult subjects with a moderate contusion injury. Previous observations showed that this stimulation paradigm induces a learning deficit and undermines functional recovery following SCI (Crown et al., 2002; Behav. Neurosci. 116:1032-1051). We now show that noxious stimulation shortly after SCI significantly increases the onset and maintenance of mechanical allodynia in adult rats with a moderate spinal cord contusion injury. Surprisingly, this pro-nociceptive response is accompanied by a decrease in the spinal expression of BDNF, TrkB and associated downstream signaling kinases, ERK1/2 and CAMKII.
Together, these observations suggest that injury alters how BDNF affects spinal nociceptive processing. In the absence of SCI, BDNF promotes central sensitization and spinal nociception. In contrast, after injury BDNF appears to have a protective effect that attenuates the effect of nociceptive stimulation.

SA165

Altered inhibition in dorsal horn circuits and strategies for pharmacological restoration

H. Zeilhofer

Dept of Pharmacology, University of Zurich, Zurich, Switzerland

Peripheral nerve damage and inflammation induce alterations in synaptic inhibition in neuronal circuits of the spinal dorsal horn through a variety of different processes, including changes in the transmembrane chloride gradient of dorsal horn neurons, changes in the synthesis of neurotransmitters and alterations in the function of neurotransmitter receptors (for a review see Zeilhofer et al., 2012). Such impaired inhibition commonly leads to pathologic pain syndromes manifesting in the development of hyperalgesia and allodynia, and possibly also in compromised spinal motor control. During the last five years our group has worked on the identification of pharmacological targets that would allow to restore compromised neuronal inhibition without the typical unwanted effects of typical GABAergic compounds such as the classical benzodiazepines. Using a series of GABA-A receptor point mutated mice we could demonstrate that the selective activation of GABA-A receptors containing alpha2 subunits can alleviate sensory symptoms of impaired spinal synaptic inhibition without inducing sedation (Zeilhofer et al., 2009). Other at present still underexplored possibilities may include the pharmacological potentiation of inhibitory glycine receptors (Yevenes & Zeilhofer, 2011). Recent work indicates that certain structural analogues of endocannabinoids act as allosteric modulators of inhibitory glycine receptors. Evidence from different groups suggests that such compounds also reverse pathological pain syndromes in different rodent models.

Regulation and roles of the $Na^+HCO_3^-$ cotransporter NBCn1 (SLC4A7) and the Na^+/H^+ exchanger NHE1 (SLC9A1) in breast cancer

S.F. Pedersen

Department of Biology, University of Copenhagen, Copenhagen, Denmark

Within the last decade it has become increasingly clear that dysregulated expression, splicing, and/or function of ion transporters and channels occurs in all cancers and contributes importantly to cancer development (1,2). Being linked to essentially all of the widely accepted hallmarks of cancer, ion transporters and channels represent novel therapeutic, diagnostic and prognostic targets. Our research group has focused in particular on dysregulation of pH regulatory ion transport in breast cancer. A fundamental property of solid tumors is a markedly altered pH-profile compared to normal tissues, with acidic extracellular, and often alkaline intracellular pH (pH_i). This at least in part reflects their upregulated glycolytic metabolism, necessitating increased acid extrusion to maintain survival.
Whereas the Na^+/H^+ exchanger NHE1 (SLC9A1) has until recently received the majority of the attention in the context of pH (dys)regulation in cancer, our recent findings indicate that the $Na^+HCO_3^-$ cotransporter NBCn1 (SLC4A7) may be of substantial importance in this context. Expression of a constitutively active, truncated form of the ErbB2/HER2 receptor (ΔNErbB2) greatly increased pH regulatory capacity in MCF-7 human breast cancer cells, in a manner mediated by NHE1 and NBCn1 (3). After ΔNErbB2 expression or stimulation of wild-type ErbB receptors, NBCn1 was strongly upregulated at the mRNA and protein levels, and NHE1 was phosphorylated at Ser703, a known target for the 90 kDa Ribosomal S6-Kinase (p90RSK). The regulation of the NBCn1 promoter by ErbB2 signaling involves Src, Extracellular Signal Regulated Kinase (ERK), and Phosphatidyl-Inositol-3 Kinase (PI3K)-Akt signaling, as well as the transcription factor Krüppel-like 4 (KLF4), which has

been assigned important and context-dependent pro- and anti-oncogenic roles in various cancers.
In 2D cultures of MCF-7 cells NHE1 localized strongly to invadopodial rosettes, where it colocalized with the invadopodial markers cortactin, F-actin and phospho-Tyr416-Src, as well as with its known binding partners, ezrin and radixin (4). NHE1 inhibition or siRNA-mediated NHE1 knockdown potently sensitized ΔNErbB2-MCF-7 cells to cisplatin-induced apoptosis and enhanced their adhesion and 2D migration on collagen-I (3,4).
Using 2D- and 3D cell culture models mimicking various aspects of the tumor microenvironment we show that the regulation and localization of NHE1 and NBCn1 are dependent on different microenvironmental factors, and that the role of NBCn1 may become more prominent in 3D culture. Finally, using matched sets of patient tissue we show that NHE1 and NBCn1 are upregulated in primary breast carcinomas and lymph node metastases compared to normal breast tissue, and we demonstrate that $Na^+HCO_3^-$ cotransport is a major determinant of pH_i regulation in freshly dissected human breast tumors (5).
In conclusion, expression and activity of the two major pH regulatory ion transporters NBCn1 and NHE1 are altered in human breast cancer, resulting in altered pH regulation. NBCn1 expression is strongly sensitive to ErbB receptor activity, and NHE1 regulates chemotherapy sensitivity and cell motility. We suggest that NHE1 and NBCn1 are potential targets in breast cancer diagnosis and/or treatment.

Physiological role of Na+-coupled HCO–3 transporters deduced from knockout studies

A. Sinning[1,2], L. Liebmann[1] and C.A. Huebner[1]

[1]Human Genetics, University Hospital Jena, Mainz, Germany and [2]Physiology and Pathophysiology, University Hospital Mainz, Mainz, Germany

Cellular ion homeostasis and pH regulation critically depend on the activity of ion exchangers. This is of special importance in the brain, where pH modulates neuronal excitability and neuronal activity in turn can cause changes in pH. The objective of our studies were the investigation of the physiological function of the Na+-coupled anion-exchanger Slc4a8 in the mammalian brain, as well as a comparative analysis of the closely related transporter Slc4a10 with the help of knockout mouse models.
Both anion exchanger are expressed broadly in neurons. Supporting an important role of Slc4a8 for neuronal pH regulation, cultured hippocampal neurons of mice with a targeted disruption of Slc4a8 showed a reduced steady-state pHi and recovered more slowly from an acute acid load. In accordance with enrichment of Slc4a8 in presynaptic nerve endings of pyramidal neurons, the electrophysiological analysis revealed a pH-dependent presynaptic defect with impaired glutamate release. Whereas, release of the inhibitory neurotransmitter GABA was not affected. The decrease of hippocampal excitability in Slc4a8-/- slices in vitro was reflected by an increased seizure threshold in vivo. Accordingly, these results of our studies propose that Slc4a8 in the brain modulates glutamate release and thus synaptic strength in a pH-dependent way.
In contrast, Slc4a10 shows a distinct neuronal expression, partly overlapping but mostly amendatory to Slc4a8. The newest results of our group suggest a crucial role of Slc4a10 for GABAergic inhibition.
Thus, these results suggest important roles of Slc4a8 and Slc4a10 for brain function and support their importance as possible targets for clinical applications e.g. in the future treatment of epilepsy.

Role of exofacial carbonic anhydrase, Na-HCO_3 co-transport, and connexin channels in the spatial control of intracellular pH in multicellular tumour cell growths and myocardial tissue

R.D. Vaughan-Jones[1], P. Swietach[1], C. Garciarena[1], A. Moreno[2], A. Hulikova[1] and K.W. Spitzer[2]

[1]Department of Physiology Anatomy & Genetics, 1 Burdon Sanderson Cardiac Science Centre, Oxford, UK and [2]Cardiovascular Research & Training Institute, Salt Lake City, UT, USA

A sufficiently high intracellular pH (Ph_i) is permissive for cell survival, growth, function and proliferation. High metabolic production of H^+ ions is compensated for by acid extrusion on ion transport proteins such as Na/H exchange (NHE) and Na-HCO_3 co-transport (NBC). This helps to regularise pH_i in individual cells. In addition, H^+-ion cross-talk between adjacent cells helps to co-ordinate pH_i throughout the tissue. The talk will contrast two different pH_i-co-ordination strategies. One is common in poorly vascularised developing tumours and relies on the activity of exofacial carbonic anhyrase enzymes, notably HIF-activated CAIX, which facilitates the venting of cellular CO_2. The other, which is common in the heart, is the buffer-shuttling of acid via histidyl dipeptides (HDPs) and CO_2/HCO_3^- between cells, through gap junctions (predominantly Cx43 channels in the myocardium).
Extracellular CAIX operates in concert with membrane HCO_3^- influx on NBC. CAIX up-regulation in hypoxic zones is associated with down-regulation of cytoplasmic CAs such as CAII. NBCs are constitutively expressed at high basal activity in a wide range of tumour cell-lines, unlike NHE1 that can be at either high or low functional level. By facilitating CO_2 diffusion out of cells, CAIX raises pH_i and reduces pHo, producing the functional hall-mark of aggressive cancer. Down regulation of CAIX activity, either by genetic manipulation or by pharma-

cological inhibition, typically results in a more acidic core pH_i in 3-D spheroid growths (eg. RT112; HCT116), a more heterogeneous spatial pH_i distribution, and a more alkaline pH in the restricted extracellular spaces.
Gap-junctional channels tend to be repressed in developing tumours, but they are commonly expressed in most healthy tissues. Cx43 channels in the myocardium mediate high passive H^+ flux whenever $[H^+]_i$ differences are presented across junctional regions. High H^+-flux is achieved by reversible binding to intrinsic HDPs (carnsoine, anserine, homocarnosine) that are present in cytoplasm (~15mM), and which readily permeate the junction. HCO_3 anion flux through the channels also enhances cell-cell H^+ transmission. The H^+ and HCO_{3-} flux is gated by moderate $[H^+]_i$ and high $[H^+]_i$ which increases and reduces Cx43 channel permeability respectively. These are acute channel-gating phenomena, also observed for Cx43 channels stably transfected into Hela or N2A cell-pairs. Because buffer permeation of Cx43 channels is high, so is cell-cell H^+ ion transmission. The system provides for spatial H^+ communication and permits slow H^+ diffusive equilibration of pH_i in tissue, resulting in a pH_i syncitium that regularises cell function. H^+-gating of cell-cell H^+ flux (autoregulation) is absent when the cytoplasmic tail of Cx43 sub-units is truncated. The talk will compare the kinetics and spatial outreach of CAIX and Cx43 mediated pH_i control, highlighting the potential advantages of each mechanism.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Should I stay or should I go? – Regulating Orai function

D. Alansary, K. Doerr, T. Kilch, C. Peinelt, I. Bogeski and B.A. Niemeyer

Biophysics, Saarland University, Homburg, Germany

Ca2+ release-activated Ca2+ (CRAC) channels were originally identified as store-operated highly selective Ca2+ channels in primary rat mast cells and Jurkat T cells (Hoth & Penner, 1992; Zweifach & Lewis, 1993), but have since been identified in many cell types. While STIM1 and Orai1 constitute the main subunits of CRAC channels in lymphocytes, other cell types contain different combinations/ratios of Orai1, Orai2 or Orai3 and STIM1 or STIM2. We are interested in physiological and pathophysiological regulation of CRAC channels by environmental factors such as oxidation, as well as by posttranslational alterations of their glycosylation status. We have shown that Orai1 channels but not Orai3 channels are inhibited by extracellular applied ROS and that C195 is mainly responsible for mediating this effect (Bogeski et al, 2010). But how does oxidation of C195 affect function? What if the channels are heteromers between Orai1 and Orai3? Current studies investigate these questions by analyzing diffusional properties (FRAP), clustering (TIRF) and heteromerization of Orai channels. In addition to functional regulation by extracellular ROS, we are interested to find out if and how T-cell function controlled by CRAC is regulated by altered glycosylation patterns. Changes in the extracellular composition of T-cell glycans are likely involved in physiological and pathophysiological dysregulation of T-cell function during ageing and in certain diseases, e.g. diabetes. Both STIM proteins are predominantly ER resident proteins showing basal glycosylation patterns. Mutations of the N-glycosylation sites of STIM1 regulate Ca2+ influx by altered oligomerization of STIM1 and by destabilization of the Ca2+ channel Orai1 (Kilch et al, 2013). In contrast, Orai1 is a complex glycosylated protein. We show that Orai1 glycosylation is cell-type specific and that given the correct repertoire of specific glycosyltransferases the glyco-fingerprint of Orai1 can affect localization and function in calcium signaling.

Physiological functions of store-operated calcium entry

J. Putney and N. Steinckwich-Besancon

NIEHS, Research Triangle Park, NC, USA

Our laboratory has been investigating the functions of store-operated Ca2+ entry (SOCE) in various physiological contexts by a combined strategy employing cell lines together with genetically modified mouse models. We disclosed significant roles for store-operated channels in the development and function of bone cells, both osteoclasts and osteoblasts; in lacrimal gland function; in differentiation of keratinocytes as well as in their role in wound healing. In this presentation, I will discuss our recent work on the role of store-operated Ca2+ channels in chemotaxing neutrophils.
Chemotaxis is essential for neutrophils to locate sites of inflammation. The formylated chemotactic peptide, fMLF, is an agonist for FRPR1 receptors through which it activates phospholipase C and induces Ca2+ release from intracellular endoplasmic reticulum stores. We first investigated the Ca2+ dependence of chemotaxis in the differentiated HL-60 cell model. Using a transwell assay, we determined that chemotaxis, but not undirected movement, is completely lost in the absence of extracellular Ca2+ or in the presence of the SOCE inhibitor, Gd3+. In many cell types, STIM1, a Ca2+ sensor protein resident in the endoplasmic reticulum, detects the extent of Ca2+ depletion and communicates this to plasma membrane Orai calcium channels to activate SOCE. In addition, STIM1 is known to play a role in organizing the organellar structure of cells through an interaction with the microtubule network. Down regulation by siRNA of STIM1 or its channel partner, Orai1, revealed that both proteins are required for chemotaxis. We over-expressed an eYFP-tagged STIM1, which augmented fMLF-induced Ca2+ signaling, as well as fMLF-induced chemotaxis. We followed the localization of eYFP-STIM1 by confocal microscopy. Chemotaxing cells polarize and move in a crawling way to a target which in this study was a micro-pipette releasing fMLF. During chemotaxis, STIM1 cellular localization was not homogeneous but rather STIM1 accumulated in the rear of migrating cells, the uropode.

We analyzed the effect of STIM1 knock out in neutrophils, in vivo, in a conditional STIM1fl/fl LyzM+/+ knockout mouse model. Treatment of mice with imiquimod cream induced a psoriasis-like skin condition and induced neutrophil migration into the skin. STIM1fl/fl LyzM+/+ knockout mice had significantly less infiltrated neutrophils in the epidermis than control mice. Together, our results suggest that Ca2+ signaling, involving SOCE, is necessary for chemotaxis in vitro and in vivo. STIM1, and by inference SOCE, may play a role in the spatiotemporal dynamics of the uropode. These findings provide new insights to our understanding of how intracellular Ca2+ changes orchestrate the cellular behavior underlying chemotactic directional movement.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Decoding calcium signalings for cancer progression

Y. Chen[1], Y. Chen[2], W. Chiu[2] and M. Shen[1,3]

[1]Pharmacology, National Cheng Kung University, Tainan City, Taiwan, [2]Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan and [3]Obstetrics and Gynecology, National Cheng Kung University Hospital, Tainan, Taiwan

The remodeling of Ca^{2+} homeostasis has been suggested as an important event in driving the expression of the malignant phenotypes, such as proliferation, migration, invasion, and metastasis. Store-operated Ca^{2+} entry (SOCE) is a predominant Ca^{2+} entry pathway in epithelial cells. Stromal-interaction molecule 1 (STIM1) is an endoplasmic reticulum (ER) Ca^{2+} sensor that triggers SOCE. The functional significance of STIM1-dependent Ca^{2+} signalings in cancer development and progression has been emerged from studies on breast and cervical cancers. STIM1 overexpression in tumor tissue was noted in 71% cases of early-stage cervical cancer. Tumor expression level of STIM1 was significantly associated with the risk of metastasis and survival, suggesting a diagnostic and prognostic value of STIM1. STIM1-dependent Ca^{2+} signalings are important for cervical cancer growth, migration, and angiogenesis. Interference with STIM1 expression or blockade of SOCE activity inhibited tumor growth and angiogenesis in animal models, confirming the crucial role of STIM1-mediated Ca^{2+} influx in aggravating tumor development *in vivo*. Mechanistic investigations revealed that STIM1 regulates the production of vascular endothelial growth factor (VEGF), a critical stimulator for tumor angiogenesis, from cervical cancer cells. Because of an increase of p21 protein levels and a decrease of Cdc25C protein levels, STIM1-silencing in cervical cancer cells significantly inhibited cell proliferation by arresting the cell cycle at the S and G2/M phases. SOCE activities as well as STIM1 expression were required for epidermal growth factor (EGF)-stimulated cancer cell migration. EGF could stimulate the aggregation and translocation of STIM1 towards to the Orai1-containing regions to mediate SOCE. STIM1-dependent SOCE was necessary for the activation of Ca^{2+}-regulated protease calpain and Ca^{2+}-regulated cytoplasmic kinase Pyk2, which regulated the focal-adhesion dynamics of migratory cervical cancer cells. STIM1 silencing also inhibited the recruitment and association of active focal adhesion kinase (FAK) and talin at focal adhesions, indicating the blockade of force transduction from integrin signaling. EGF-induced phosphorylation of myosin II regulatory light chains and actomyosin formation were dependent on STIM1-mediated Ca^{2+} entry. The direct measurement of cell traction forces revealed that STIM1-dependent Ca^{2+} signaling regulated the traction force generation at cell adhesions. Taken together, these results highlight the potential role of STIM1-dependent signaling as a target to interfere with cancer malignant behaviors.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA172

STIM proteins, Ca2+ oscillations and gene expression

P. Kar and A. Parekh

Oxford University, Oxford, UK

Stimulation of cells with physiological concentrations of calcium-mobilising agonists often results in the generation of repetitive cytoplasmic Ca2+ oscillations. Although oscillations arise from regenerative Ca2+ release, they are sustained by store-operated Ca2+ entry through CRAC channels. Ca2+ nanodomains near CRAC channels that open during the oscillatory cycle recruit local signalling pathways that lead to activation of NFAT transcription factors and increased expression of genes including c-fos and tumour necrosis factor-α. Stores communicate with CRAC channels through the ER Ca2+-sensing proteins STIM1 and STIM2. In this talk, we will describe our recent experiments that address the relative roles of STIM1 and STIM2 in maintaining Ca2+ oscillations and gene expression in mast cells. Our results reveal that different agonists utilise different STIM proteins to support Ca2+ signals and subsequent downstream responses. We will also compare gene knockdown strategies with pharmacological block of STIM proteins to address their relative contributions to physiological levels of Ca2+ signalling.

Work in our laboratory is supported by the MRC.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA173

Native neuronal Kv4-encoded channels function in macromolecular protein complexes

J.M. Nerbonne

Developmental Biology, Washington University Medical School, St. Louis, MO, USA

Voltage-gated K+ (Kv) channels are key determinants of membrane excitability in the peripheral and in the central nervous systems, functioning to control the resting membrane potentials, the waveforms of action potentials and the repetitive firing properties of individual neurons. In addition, by influencing presynaptic neurotransmitter release and the postsynaptic responses to neurotransmitters, Kv channels regulate the integrative properties of neurons and modulate synaptic potentiation and depression. Electrophysiological studies have distinguished multiple types of Kv currents, based on differences in kinetic, voltage-dependent and/or pharmacological properties, both central and peripheral neurons. Indeed, in most neurons, multiple types of Kv channels with unique time- and voltage-dependent properties, as well as with distinct cellular and subcellular distribution patterns and functional roles, are co-expressed. Consistent with the apparent functional diversity of native neuronal Kv channels, multiple subfamilies of Kv channel pore-forming (α) subunits, as well as numerous putative Kv channel accessory subunits and regulatory proteins, have been identified and shown to be differentially expressed in neurons, as well as in other cell types. Rapidly activating, inactivating and recovering Kv currents, typically referred to as A-type Kv currents (IA), for example, have been shown to be expressed in many peripheral and central neu-

rons and to regulate input resistances, action potential durations, repetitive firing rates and the back-propagation of action potentials into dendrites, and to modulate the responses to synaptic inputs and influence synaptic plasticity. Interestingly, Kv currents with very similar biophysical properties, referred to as Ito,f (fast transient outward Kv currents), have been identified in mammalian cardiac myocytes and shown to control the early phase of myocardial action potential repolarization. Interestingly, a number of recent studies have demonstrated critical roles for pore-forming (α) subunits of the Kv4 subfamily, particularly Kv4.2 and Kv4.3, but also Kv4.1, in the generation of native neuronal IA channels, as well as in the generation of native cardiac Ito,f channels. Studies in heterologous cells have also suggested potential functional roles for a number of transmembrane and cytosolic Kv channel accessory proteins, including members of the minK/MiRP (minimal K+ channel), KChIP (K+ channel interacting protein) and DPP (dipeptidyl peptidase) subfamilies of Kv channel accessory subunits, in the generation of Kv4-encoded channels. Although the results of recent studies using targeted "knockdown" and "knockout" strategies to define directly the physiological role(s) Kv4 channel accessory subunits in determining the functional cell surface expression and the biophysical properties of native Kv4-encoded neuronal IA (and myocardial Ito,f) channels are consistent with some of the results obtained in heterologous overexpression studies, novel physiological roles have also been revealed. In addition, the application of quantitative mass spectrometry-based proteomic analysis as a rapid and unbiased approach to identify the components of native Kv4-encoded neuronal IA (and myocardial Ito,f) channel macromolecular protein complexes has, in addition to confirming association between Kv4 α subunits and the KChIPx and DPPx accessory subunits in brain, also identified a number of novel Kv channel accessory/regulatory proteins. Multiple experimental approaches, exploited in parallel to define the physiological roles of newly identified, putative channel accessory and regulatory subunits in the generation of native neuronal IA channels, will also be discussed.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA174

Dynamic aspects of the subunit stoichiometry of the KCNQ/KCNE channel complex

K. Nakajo[1,2] and Y. Kubo[1,2]

[1]Div Biophys & Neurobiol, National Institte for Physiological Sciences, Okazaki, Aichi, Japan and [2]Dept Physiol Sci, Graduate Univ for Advanced Studies, Hayama, Kanagawa, Japan

KCNQ1 is a voltage-gated potassium channel α subunit. KCNQ1 forms a tetramer and gives rise to K^+ conductance in many tissues such as heart, inner ear, kidney, intestine and pancreas. Biophysical properties of KCNQ1 are dynamically modulated by the presence of KCNE proteins. KCNE1, for example, increases KCNQ1 current amplitude, slows down the activation and deactivation kinetics and greatly shifts the conductance-voltage (G-V) curve in the positive (depolarizing) direction. This KCNQ1-KCNE1 complex underlies the slowly-activating K^+ current called I_{Ks} in the heart, and regulates the excitability of cardiac myocytes. KCNE3, co-expressed with KCNQ1 in the intestine, makes KCNQ1 channel constitutively-active. Therefore, the subunit organization of KCNQ1-KCNE complex is essential for the ion channel properties and the physiological functions of KCNQ1.

One of the fundamental questions for KCNQ1 channel is the stoichiometry of KCNQ1-KCNE complex. Previous works indicate the stoichiometry of KCNQ1 and KCNE1 is fixed at 4:2; two KCNE1 proteins bind to a tetrameric KCNQ1 channel. We recently applied the subunit counting method using single GFP molecule imaging to address this question (Nakajo et al. 2010). KCNE1-GFP fusion protein was co-expressed with KCNQ1 channels in *Xenopus* oocytes. Using a total internal reflection microscope, a single bleaching event from a single GFP molecule tagged to KCNE1 protein was observed as a step-wise reduction of fluorescence. The number of KCNE1 proteins in a single ion channel complex can be estimated by the number of bleaching events from a single optical spot. By counting the number of KCNE1 proteins, we found that some of the KCNQ1 ion channel complexes contain four KCNE1 proteins. This result indicates that "4:4" channel (four KCNQ1 subunits with four KCNE1 subunits) does exist. Interestingly, the number of KCNE1 proteins in KCNQ1 channel complex was not fixed but variable. More KCNE1 proteins are expressed, more "4:4" channels are produced. Because "4:4" channel showed slower activation kinetics compared to "4:2" channel, an increase in KCNE1 expression may elevate the excitability of cardiac myocytes.

Our results imply that the dynamic interaction between KCNQ1 and KCNE proteins may occur on the plasmamembrane. If that is the case, KCNQ1 channels expressed on the plasmamembrane can be directly regulated by the association and dissociation of KCNE proteins. To investigate this possibility, we examined electrophysiological properties of series of tandem constructs of KCNQ1 and KCNE1 with various linker lengths. If the stoichiometry of KCNQ1-KCNE1 complex is flexible and dynamically changeable on the plasmamembrane, KCNQ1 channel properties would depend on the linker length between KCNE1 and KCNQ1. KCNE1-KCNQ1 constructs (producing "4:4" channel) showed a linker-length dependent change; as linker length increased, G-V curves were shifted to hyperpolarizing direction. On the other hand, KCNE1-KCNQ1-KCNQ1 constructs (producing "4:2" channel) showed no apparent linker-length dependent change in the G-V curves. These results suggest that 1st and 2nd KCNE1 proteins firmly bind to KCNQ1 channel while 3rd and 4th KCNE1 proteins may bind loosely. 3rd and 4th KCNE1 might dynamically regulate "4:2" channel by association/dissociation on the plasmamembrane. Further experiments are needed to prove the dynamic interaction between KCNQ1 and KCNE proteins on the plasmamembrane.

It is also important to understand how KCNE proteins regulate KCNQ1 channels. Growing evidences from different groups including us indicate that KCNE proteins give influence on the movement of the voltage-sensing domain (VSD; S1-S4 segments) of KCNQ1 channel. By using cysteine-modifying MTS reagents, we showed that the accessibility of S4 segment was significantly changed by the presence of KCNE proteins (Nakajo and Kubo, 2007). As longer depolarization was required to be modified by MTSES, we concluded that the VSD of KCNQ1 was stabilized in the "down" state. On the other hand, KCNE3 stabilized the VSD in the "up" state and that is the reason why KCNE3 makes KCNQ1 a constitutively-open channel. By comparing the amino acid sequence of human KCNQ1 to that of Ci-KCNQ1 (KCNQ1 ortholog from marine chordate *Ciona Intestinalis*), we successfully identified S1 segment of KCNQ1 as a binding site for KCNE3 protein (Nakajo et al. 2011). KCNE1 also interacts with the VSD and modifies its movement. Because KCNQ1-KCNE channel complex can form different stoichiometries, it is important to know how each

VSD is modified by KCNE proteins towards further understanding the modulation of KCNQ1 channel by KCNE proteins.

Gated motions and assembly modalities of the IKS potassium channel complex

M. Dvir[1], D. Shaham[2], I. Ben-Tal Cohen[1], R. Strulovitz[2], Y. Haitin[1], J. Hirsch[2] and B. Attali[1]

[1]Physiology, Tel Aviv University, Tel Aviv, Israel and [2]Biochemistry, Tel Aviv University, Tel Aviv, Israel

Kv7 channels (KCNQ) represent a family of voltage-gated K+ channels, which plays a prominent role in brain and cardiac excitability. Their physiological importance is underscored by the existence of mutations in human Kv7 genes, leading to severe cardiovascular and neurological disorders such as the cardiac arrhythmias and neonatal epilepsy. In the heart, the assembly of Kv7.1 with KCNE1 produces the IKS potassium current that is crucial for the late repolarization of the cardiac action potential. Mutations in either Kv7.1 or KCNE1 genes produce the long QT or short QT syndromes, which are genetically heterogeneous cardiovascular diseases, characterized by ventricular or atrial arrhythmias. The scaffolding A-kinase anchoring protein Yotiao (AKAP9) brings together PKA, PP1, PDE4D3, AC9, and the IKS channel complex to achieve regulation following β adrenergic stimulation. Kv7 channels exhibit some structural and functional features that are distinct from other Kv channels. Notably, the Kv7 family lacks the T1 tetramerization domain and it does not associate with the Kvβ subunit. Rather, it has a large intracellular C-terminal (CT) domain, ranging from 320 to 500 residues in size, bound constitutively to calmodulin. This domain is responsible for channel tetramerization, proper channel trafficking, and gating properties. Here we provide a brief overview of current insights and yet unsettled issues about the gated motions and assembly modalities of the IKS potassium channel complex. Proximal helices A and B form the site for calmodulin (CaM) binding, while distal coiled-coil helices C and D are important for channel tetrameric assembly and protein interactions. We studied the interactions and voltage-dependent motions of IKS channel intra-cellular domains, using fluorescence resonance energy transfer combined with voltage-clamp recording and in-vitro binding of purified proteins. The results indicate that the KCNE1 distal C-terminus interacts with the coiled-coil helix C of the Kv7.1 tetramerization domain. This association is important for IKS channel assembly rules as underscored by Kv7.1 current inhibition produced by a dominant-negative C-terminal domain. Upon channel opening, the C-termini of Kv7.1 and KCNE1 come close together. Co-expression of Kv7.1 with the KCNE1 long QT mutant D76N abolished the K+ currents and gated motions. Thus, during channel gating KCNE1 is not static. Instead, the C-termini of both subunits experience molecular motions, which are disrupted by the D76N causing disease mutation. We investigated the structure of the membrane proximal CT module in complex with CaM by x-ray crystallography. The results show that CaM intimately hugs a two helical-bundle. Biochemical data, structure-based mutagenesis of this module in the context of concatemeric channels and functional analysis lead us to conclude that one CaM binds to one individual protomer, without crosslinking subunits and that this configuration is required for proper channel expression. Molecular modeling of the CT/CaM complex in conjunction with small-angle X-ray scattering and electrophysiology suggest that the membrane proximal region, with a rigid lever arm is a critical gating module. We examined the effect of long QT mutations located at the C-terminal interface of the two subunits. Our results suggest that the distal KCNE1 C-terminus, probably via its interaction with the coiled-coil helix C, is a crucial determinant for the functional modulation of Kv7.1 by Yotiao-mediated PKA phosphorylation.

The regulation of KCNQ channels by phosphoinositides

S.C. Harmer

William Harvey Heart Centre, Queen Mary University of London, London, UK

Membrane phosphoinositides, and in particular phosphatidylinositol (4,5)-bisphosphate (PIP_2), have been shown to be important for the function of the five members of the KCNQ channel family (KCNQ1-5). In general, our studies have primarily focussed on their actions on KCNQ1. KCNQ1 combines with the auxiliary subunit KCNE1 to form a heteromultimeric channel complex which underlies the cardiac delayed rectifier current I_{Ks}. The activity of this channel can be regulated through $G_{q/11}$-coupled receptors and downstream phospholipase-C (PLC) activation. The activation of PLC leads to I_{Ks} channel inactivation and it is now thought that this occurs due to the hydrolysis of plasma membrane bound PIP_2. In detail, the depletion of PIP_2 leads to channel inactivation by acting to slow the rate of channel activation and increase the rate of channel deactivation and these effects combine to result in a large shift in the voltage dependence of channel activation ($V_{0.5}$) towards depolarised potentials. Although PIP_2 acutely modulates I_{Ks} channel function, the nature of the molecular interactions and the specific residues involved in the binding of PIP_2 to this channel had not been established. Using a combination of biochemical and electrophysiological techniques we have identified that a cluster of basic residues (Lys-354, Lys-358, Arg-360 and Lys-362), located just after the S6 domain in the proximal C-terminus, are crucial for the binding of a range of anionic phospholipids, including PIP_2. The mutation of these charged residues to alanine, singly or in combination, results in a loss of binding to anionic phospholipids and acts to mimic the electrophysiological effects of PIP_2 depletion on channel function by causing a positive shift in the $V_{0.5}$. Our data also suggest that the two middle residues (Lys-358 and Arg-360), which form the core of the charge cluster, appear to be particularly important as their mutation in combination results in a complete loss of binding to PIP_2 (and a range of other phosphoinositides) and a dramatic shift (~+60 mV) in the $V_{0.5}$. Given that the charged residues we have identified in KCNQ1 appear in general to be well conserved in homologous positions in the other members of the KCNQ family it

raises the possibility that the effects of PIP_2 on these channels could also be mediated through similarly located charge clusters. To investigate this possibility we have recently, in collaboration, analysed whether the mutation, to alanine, of homologous residues in KCNQ2 acts to alter this channels response to PIP_2. Interestingly, the mutation of Arg-325 (which is homologous to Arg-360 in KCNQ1) results in a ~60% reduction in current density, without change in the $V_{0.5}$, and an approximately eight-fold reduction in the sensitivity of the channel to activation by an exogenously applied water soluble derivative of PIP_2. In summary, we have identified that charged residues located in the proximal C-terminus of KCNQ1 and in a homologous region in KCNQ2 are involved in regulating the response of these channels to PIP_2. Whether the actions of PIP_2 on the remaining members of the KCNQ family are mediated through similarly located charge clusters remains to be determined.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA177

Role of KCNQ4 K+ channels in sensory biology

T.J. Jentsch

FMP/MDC, Berlin, Germany

Human pathologies associated with KCNQ channels include cardiac arrhythmias, deafness, and epilepsy. We have shown previously that the KCNQ4 K+ channel underlies a form of dominant human hearing loss (1) and have generated mouse models which showed that this pathology is owed to a degeneration of cochlear sensory outer hair cells (OHCs) that depolarize in the absence of KCNQ4 (3). KCNQ4 localizes to the base of OHCs and is also found at calyx synapses of type vestibular hair cells and selected tracts and nuclei of the brainstem (2). In contrast to cochlear hair cells, KCNQ4 is expressed postsynaptically at vestibular hair cell synapses, where it may contribute to remove K+ from the synaptic cleft (4). Mice lacking KCNQ4 show discrete vestibular symptoms which have also been observed in some humans with KCNQ4-related hearing loss.

The expression of KCNQ4 in trigeminal ganglia (2) prompted us to examine its expression in dorsal root ganglia (DRGs). Indeed, we found KCNQ4 to be expressed in a subset of large diameter DRG neurons (5). These innervate a subset of rapidly adapting skin mechanoreceptors, where they localize to sensory nerve endings. Both our Kcnq4 mouse models, as well as patients with KCNQ4 mutations, showed altered skin mechanoreception (5). KCNQ4 tunes the response of mechanoreceptors to their optimal frequencies. KCNQ4 has multiple, rather unrelated roles in sensory biology.

Therapeutic potential of endothelial growth factors and receptors

K. Alitalo

Wihuri Research Institute, Helsinki, Finland and Translational Cancer Biology Research Program, University of Helsinki, Helsinki, Finland

Cancer and cardiovascular diseases are the leading causes of morbidity and mortality in the developed countries. Current cardiovascular and cancer therapies are often insufficient, unsuccessful or not suitable for all patients, thus novel therapies are urgently needed. Inhibition of angiogenesis is already used in the clinics, but with limited success. On the other hand, stimulation of the growth of blood vessels, angiogenesis, and of arteriogenesis has been unsuccessfully tried for the treatment of tissue ischemia in humans. The elucidation of disease-related functions of endothelial growth factors and their signal transduction in cancer and cardiovascular disease should help in development of improved therapy for these diseases. Possible new therapy requires on solid knowledge of the biology of vascular endothelial growth factors, angiopoietins, angiogenesis and lymphangiogenesis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA179

Distinguishing neuropilin signalling in angiogenesis, arteriogenesis and vascular permeability

C. Ruhrberg

UCL, London, UK

Vascular morphogenesis requires the complementary processes of vasculogenesis, angiogenesis and arteriogenesis. All three processes are VEGF-A dependent, but how VEGF-A signalling is regulated to selectively stimulate each one at the appropriate time is poorly understood. The VEGF-A isoform specific receptor neuropilin 1 (NRP1) contributes to both angiogenesis and arteriogenesis and has additionally been implicated in vascular permeability. We find that mice expressing solely a truncated form of NRP1 lacking the cytoplasmic domain have normal angiogenesis. In contrast, they show reduced arteriogenesis, similar to mice lacking synectin/GIPC1, which binds the NRP1 cytoplasmic domain. Tissue culture studies linked the arteriogenic defect to impaired VEGFR2 endocytosis downstream of VEGF-A activation, which increased dephosphorylation of the VEGFR2 site that activates ERK1/2

signalling. Mice lacking the NRP1 cytoplasmic tail also showed reduced VEGF-A induced vascular permeability, but, synectin was not required for the permeability response. Taken together, these findings suggest that the membrane-anchored extracellular domain of NRP1 is sufficient for angiogenesis, whilst arteriogenesis and vascular permeability additionally require the NRP1 cytoplasmic tail, with a differential dependence on synectin.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Formation of microvascular networks: role of stromal interactions directing endothelial growth

J.B. Hoying[1], U. Utzinger[2] and J.A. Weiss[3]

[1]Cardiovascular Therapeutics, Cardiovascular Innovation Institute, Louisville, KY, USA, [2]Biomedical Engineering, University of Arizona, Tucson, AZ, USA and [3]Bioengineering, University of Utah, Salt Lake City, UT, USA

In the adult, angiogenesis leads to an expanded microvascular network as new vessel segments are added to an existing microcirculation(1). This necessarily means that growing neovessels must navigate through tissue stroma as they locate and grow towards other neovessels and/or existing vessels of the parent network. We have a growing body of evidence demonstrating that angiogenic neovessels reciprocally interact with the stromal environment (interstitial matrix and stromal cells) resulting in persistent and directed neovascular growth during angiogenesis(2-4). Given the malleability of matrix elements and the viscoelastic properties of collagen gels, neovessel guidance by the stroma is likely due to perpendicular compressive forces arising from active tissue deformation. These similar stromal influences can also control the final network topology of the new microcirculation, including the distribution of arterioles, capillaries and venules(5). In this case, stromal-derived stimuli must be present during the post-angiogenesis remodeling and maturation phases of neovascularization in order to have this effect. Interestingly, the pre-existing organization of vessels prior to the start of angiogenesis has no lasting influence on the final, new network architecture. Additionally, we have new evidence that tissue stromal cells enable the invasion of growing neovessels across interstitial matrix interfaces during angiogenesis through a paracrine-dependent process. Importantly, stromal cells need to be spatially near the growing neovessels suggesting a local, but as of yet undefined, interaction. Combined, the evidence describes interplay between angiogenic neovessels and stroma that is important in directed neovessel growth and invasion. This dynamic is also likely a mechanism by which global tissue forces influence vascular form and function.

The intermediate filament cytoskeleton plays a key role in endothelial sprout initiation

K.J. Bayless[1], H. Kang[1], C.L. Duran[1], C.A. Abbey[1], H. Kwak[1], J.M. Dave[1], R.R. Kaunas[2] and S.A. Maxwell[1]

Endothelial cells normally line the vasculature and remain quiescent. However, these cells can be rapidly stimulated to initiate new blood vessel formation given the proper cues. This study reports a new mechanism for initiating angiogenic sprout formation that involves vimentin, the major intermediate filament protein in endothelial cells. We utilized two models to stimulate endothelial sprouting responses into three-dimensional collagen matrices, where sphingosine 1-phosphate (S1P) was combined with either growth factors (GF) or wall shear stress (WSS). Initial studies confirmed vimentin was required for both S1P + GF- and S1P + WSS-induced endothelial cell invasion. We also observed that vimentin was cleaved by calpains during invasion. Calpains were predominantly activated by GF and were required for sprout initiation. Because others have reported membrane type 1 – matrix metalloproteinase (MT1-MMP) is required for endothelial sprouting responses, we tested whether vimentin and calpain acted upstream of MT1-MMP. Both calpain and vimentin were required for successful MT1-MMP membrane translocation in both invasion systems, which shared a common activation by S1P. In addition, vimentin complexed with MT1-MMP in a manner that required both the cytoplasmic domain of MT1-MMP and calpain activation, which increased the soluble pool of vimentin in endothelial cells. Altogether, these in vitro data indicate that pro-angiogenic signals converge to activate calpain-dependent vimentin cleavage and increase vimentin solubility, which act upstream to facilitate MT1-MMP membrane translocation, resulting in successful endothelial sprout formation in three-dimensional collagen matrices. To confirm these data in an in vivo model, wound healing studies were conducted in mice anesthetized with a ketamine/xylazine cocktail in an acceptable plane of anesthesia. Mice were treated with FTY720, a pharmacological antagonist of S1P or vehicle control. Compared to vehicle, FTY720 treatment significantly reduced vascular density at 9 days of wound healing. In addition, mice lacking vimentin exhibited reduced angiogenic responses compared to wild-type littermates. These data help reinforce a requirement for S1P in angiogenic responses in vivo, as well as a critical role for vimentin in angiogenic responses during wound healing. In addition, these findings help explain why S1P synergizes with GF and WSS to stimulate robust sprouting in 3D collagen matrices.

Recruitment and role of platelets and leukocytes in models of infection and immunity

P. Kubes

Physiology and Pharmacology, University of Calgary, Calgary, AB, Canada

The hemocyte plays the role of both platelets and leukocytes in invertebrates. In mammals, two separate cell types exist including the platelet which has been assigned the role of hemostasis and the neutrophil which is an innate immune cell involved in fighting infection. However this separation is somewhat artificial and probably does not accurately represent the function of platelets and neutrophils. In fact the platelet likely contributes to both sterile inflammation and in host response to infections. In sterile injury in for example the liver the platelet arrives at sites of injury in seconds plugging sinusoids. This occurs via certain integrins and functions to permit the neutrophil to gain access to the site of injury. In infection in the liver, the platelet also contributes meaningfully. In fact, we have identified a novel patrolling mechanism for platelets in the sinusoids where a touch and go interaction continuously occurs with the intravascular macrophage of the liver, the Kupffer cell. When a bacterium is caught by Kupffer cells, the platelets touch but don't let go and form an encapsulation around the microbe and prevent dissemination. If the microbe persists in the vasculature, the platelet also binds neutrophils and induces the formation of Neutrophil Extracellular Traps in the vasculature thereby helping to catch intravascular free-flowing bacteria. In fact the trapping can be improved 4-fold above the constitutive Kupffer cell trapping of bacteria. Clearly the platelet contributes to neutrophil recruitment to sites of sterile injury as well as to neutrophil and macrophage function to help eradicate infections.

Leukocyte recruitment during angiogenesis

M. Phillipson

Medical cell biology, Uppsala University, Uppsala, Sweden

Blood vessel growth, angiogenesis, is a tightly regulated process involving not only endothelial cells, but also several different cell types. Leukocytes are known to accumulate at sites of hypoxia and were recently identified as key players in the process of vessel neo-formation. Recognition of leukocyte involvement in angiogenesis has unlocked a new research area especially focusing on tumor vascularization, but the dynamics of leukocyte involvement in angiogenesis, as well as their exact pro-angiogenic actions are still largely unknown. To address this, we developed a model that allows for in vivo visualization and tracking of leukocytes at the site of angiogenesis.
Isolated pancreatic islets are transplanted to the cremaster muscle of genetically identical recipient mice. Leukocytes, endothelial cells and blood flow at the site of islet transplantation are studied in parallel at different time points following transplantation using high-speed in vivo confocal microscopy. We found that isolated islets transplanted to striated muscle rapidly regained their dense, glomeruli-like capillary network. Neutrophils were crucial for initiation of this process and islets transplanted to neutropenic mice did not become revascularized. In fact, a distinct neutrophil subset with proangiogenic actions was recruited from the circulation to the site of hypoxia by islet-derived vascular endothelial growth factor A (VEGF-A), the main angiogenic factor. Proinflammatory neutrophils were not recruited by VEGF-A and expressed distinct lower levels of the chemokine receptor CXCR4 compared to the proangiogenic subset. Proangiogenic neutrophils delivered highly active MMP-9 (matrix metalloproteinase 9) known to be important for angiogenesis to the site of islet transplantation. The role of neutrophil-derived MMP-9 was demonstrated by transplanting islets to MMP-9 deficient mice, which resulted in severely delayed development of the intra-islet capillary network as well as an altered vascular network at later time points following transplantation. Further, our data imply the existence of two separate neutrophil lineages already in circulation based on the levels of CXCR4. These different neutrophil subsets did not change phenotype by in vitro stimulation with MIP-2 (CXCL2) or VEGF-A. Not only neutrophils exert proangiogenic actions, and ongoing studies in my laboratory address both neutrophil and monocyte recruitment to sites of hypoxia, as well as the different roles of neutrophils and macrophages for vessel neoformation and maturation. We also track the migration pattern and cellular interactions of the different cell types to understand the respectively driving force and actions during angiogenesis.
Thus, by using a new in vivo imaging model for studying the behavior and actions of different leukocyte populations during angiogenesis, important information of their identities and actions are gained. We found that neutrophils and macrophages have very different, but profound roles and effects on the revascularization of transplanted pancreatic islets.

Regulation of endothelial junctions in leukocyte extravasation

D. Vestweber

Max Planck Institute for Molecular Biomedicine, Muenster, Germany

The formation of endothelial junctions and their regulation in patho-physiological processes is regulated by complex mechanisms that modulate the actomyosin based cytoskeleton and cell adhesion activities at endothelial contacts. The stability of endothelial junctions is centrally dependent on the adhesive function of VE-cadherin. We have recently shown that knock in mice expressing a fusion protein consisting of VE-cadherin and α-catenin instead of wt VE-cadherin are strongly impaired

in VEGF- or histamine-induced vascular permeability and in cytokine-induced recruitment of leukocytes into various inflamed tissues. These results demonstrate that both processes require in vivo interference with the adhesive function of VE-cadherin.

In vitro studies have suggested that the phosphorylation of certain tyrosine residues in VE-cadherin is involved in the induction of transendothelial permeability and transmigration of leukocytes through cultured endothelial cell layers. In agreement with this, we found that the endothelial specific receptor type protein tyrosine phosphatase, VE-PTP, associates with VE-cadherin and supports its adhesive function. We showed recently that the dissociation of VE-PTP from VE-cadherin is in vivo necessary for leukocyte extravasation and induction of vascular permeability.

To analyze the relevance of tyrosine phosphorylation of VE-cadherin for the regulation of endothelial junctions in vivo we have generated knock in mice where certain tyrosine residues in VE-cadherin were replaced by phenylalanines. In addition, we generated specific antibodies for each of these different phosphorylated tyrosines within VE-cadherin. Surprisingly, we found differential regulation of the phosphorylation of these residues in vivo. Furthermore, analysis of the induction of vascular permeability and leukocyte recruitment in the different knock in mice revealed distinct roles for different tyrosine residues.

Mode and dynamics of neutrophil transmigration *in vivo*

S. Nourshargh

William Harvey Research Institute, Barts and The London Medical School, Queen Mary University of London, London, UK

Migration of leukocytes to sites of injury or inflammation is a critical component of both innate and adaptive immunity. To penetrate venular walls, leukocytes must migrate through multiple barriers, endothelial cells (EC), the pericyte sheath and the venular basement membrane (BM) 1, 2. Although there is increasing interest and understanding of the mechanisms that mediate transendothelial cell migration (TEM), the relative contribution of individual molecules requires further clarification 1, 2. Within our group we aim to investigate the mode and mechanisms of leukocyte transmigration through imaging of inflamed tissues by multiple methods, including the application of high resolution confocal intravital microscopy. With this approach we have noted previously unreported physiological responses (eg ICAM-1-mediated sub-endothelial cell crawling 3) and also potential pathological events such as "disrupted" modes of neutrophil TEM 4. The latter includes the first direct observation of in vivo neutrophil reverse TEM (rTEM) within a mammalian system, a response that we have associated with reduced expression of JAM-C from EC junctions, indicating a key role for JAM-C in regulation of polarised luminal to abluminal neutrophil TEM 4.

In investigating the pathophysiological relevance of rTEM we noted that this response was most prevalent following ischemia-reperfusion (I-R) injury and was associated with the presence of a subset of functionally primed neutrophils within the pulmonary vasculature which correlated with the development of acute lung inflammation 4. As loss of EC JAM-C from a primary site of injury/inflammation appears to be instrumental in turning a local inflammatory response to a systemic multi-organ phenomena, on-going works have aimed to elucidate the prevalence of this event and its associated mechanisms.

Overall, through rigorous analysis of leukocyte-vessel wall interactions by direct real-time imaging of inflamed tissues, our findings provide novel insights into the cellular and molecular mechanism via which leukocytes breach venular walls in vivo, findings that are likely to identify novel and disease-specific phenomena. Collectively, our findings have contributed to the developing concept that neutrophils have a broader role in inflammation, immunity and pathogenesis of inflammatory disorders than conventionally considered, emphasising the need for greater insight into the mode, mechanisms and implications of neutrophil trafficking in vivo.

Molecular correlates of pain in the anterior cingulate cortex

L. Wu

Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ, USA and Department of Physiology, University of Toronto, Toronto, ON, Canada

Glutamatergic transmission and plasticity in the brain are critical for behaviors, such as memory, addiction, and chronic pain. In the anterior cingulate cortex (ACC), a brain area related to persistent pain, peripheral inflammation caused functional alterations in NMDA receptors and glutamate release (Wu et al., 2005; Zhao et al., 2006). The mechanism underlying the regulation of glutamatergic transmission remains elucidated. Among many possible candidate molecules, cyclic AMP (cAMP) is a key second messenger for synaptic plasticity and chronic pain in the ACC. We have found impaired synaptic plasticity in the ACC (Liauw et al., 2005) and attenuated behavioral sensitization in various chronic pain models in mice lacking calmodulin-stimulated adenylyl cyclase (AC) 1 and AC8 (Wei

et al., 2002). Moreover, cAMP pathway is involved in both postsynaptic and presynaptic alterations in the ACC after chronic pain (Wu et al., 2005; Xu et al., 2008; Zhao et al., 2006). However, the dissection of the relative contributions of pre- and postsynaptic components to chronic pain in the brain is difficult. Particularly, it is unclear if changes in presynaptic glutamate release related to cAMP pathway may be sufficient to cause behavioral nociceptive responses.

In order to address this question, we took advantage of transgenic mice heterologously expressing an Aplysia octopamine receptor (Ap oa1) (Isiegas et al., 2008). This G protein coupled receptor selectively activates the cAMP pathway after binding of its natural ligand, octopamine (Chang et al., 2000), in the forebrain. Using whole cell recording of pyramidal neurons in the ACC, we found that activation of Ap oa1 by octopamine enhanced glutamatergic synaptic transmission (127.5±6.8% of control, n=11, P<0.01, paired t-test). The facilitatory effects was mediated activation of Ap oa1 at presynaptic site, as octopamine increased the frequency of miniature excitatory postsynaptic currents (from 3.9±0.9 Hz to 5.6±1.1Hz, n=8, P<0.01, paired t-test) and decreased paired pulse facilitation (1.48±0.09 to 1.28±0.06, n=14, P<0.05, paired t-test). Bilateral microinjection of octopamine into the ACC significantly facilitated behavioral responses to inflammatory pain (the formalin test, F(1,286) = 5.46, P<0.037, two-way ANOVA) but not acute pain. The present study provides the first evidence linking enhanced presynaptic glutamate release in the ACC to behavioral sensitization caused by peripheral inflammation.

Maladaptive brain plasticity in pain: amygdala and prefrontal cortex

V. Neugebauer

Neuroscience & Cell Biology, Univ. of Texas Medical Branch, Galveston, TX, USA

The amygdala is generally considered a brain center for emotions. In pain models, synaptic plasticity develops in a network of lateral (LA), basolateral (BLA) and central (CeA) nuclei. The resulting hyperactivity of CeA neurons drives amygdala-dependent pain behaviors such as emotional-affective responses (vocalizations) and anxiety. Hyperactivity of BLA neurons inhibits processing in the medial prefrontal cortex (mPFC) through “feedforward inhibition”, resulting in cognitive deficits such as impaired decision-making. Counteracting abnormal inhibition of mPFC output neurons mitigates cognitive deficits and also inhibits pain behaviors. At least part of this beneficial effect involves cortical inhibition of amygdala neurons, suggesting that strategies to restore cortical control may have therapeutic value.

Central neuronal mechanisms underlying the central post stroke pain

B. Shyu

Institute of Biomedical Sciences, Taipei, Taiwan

Approximately 8-14% of stroke victims suffer central post-stroke pain (CPSP) and such a cause of pain affects a large number of people, many of whom are not referred for proper medical evaluation or treatment. Studies that addressed the detailed mechanisms of CPSP are not well established, thus resulting in presently inadequate therapies (Bowsher, 2001). CNS inflammation arises from initial insults of ischemic and traumatic brain injuries such as stroke may give rise to increased levels of extracellular nucleotides. These extracellular nucleotides and their metabolites may activate a variety of cell surface purinergic receptors, influence the inflammatory activities among responding cells. Many of these activities are mediated through P2X receptors, and in particular, through

the activation of the subtype, P2X7 receptor (Wang X. et al., 2004). P2X7 receptors have been highly postulated to be associated with nociceptive transmission and chronic neuropathic pain. However, it still unclear is whether P2X7 receptors directly participate in pain signaling in the CPSP.

Proliferation of microglia and glia cells in dorsal root ganglia was reported in neuropathic pain induced by spinal cord injury or peripheral injury. Over expression of brain-derived neurotrophic factor (BDNF) by proliferated microglia or glia cell in dorsal root ganglia after injury was a factor related to neuropathic pain (Zhang. et al., 2011). Expression of KCC2 and NKCC1 channels of mature neuron cell could be changed after the over expression of BDNF and intracellular chloride concentration would be in an unbalance state that could cause an abnormal excitation (Jolivalt et al., 2008).

In the present study, we tested the hypothesis that persistent CPSP is caused by P2X7 receptor activation and BDNF over expression after thalamic tissue damage and subsequent elevations in inflammatory cytokines, such as IL-1β. A CPSP rat model was utilized to elucidate the characteristics of CPSP. Male Sprague-Dawley rats (300–400 g) were housed in an air-conditioned room with free access to food and water. All experiments were carried out in accordance with the guidelines of the Academia Sinica Institutional Animal Care and Utilization Committee. Type 4 collagenase (0.125U/0.5 μl) was injected into rats' lateral thalamic area. Significant hyperalgesia to mechanical and thermal pain stimulation were developed beginning 1 week after surgical CPSP induction, which persisted for at least 5-6 weeks compared with their contralateral unaffected side. P2X7 receptors and inflammatory cytokines were found highly elevated in the thalamus under CPSP conditions. Induced CPSP rats with early treatment of P2X7 antagonist exhibited reduction of hyperalgesia and hyper neuronal excitability. Early treatment with P2X7 receptor antagonist also blocked the enrichment of microglia aggregation and elevated P2X7, TNF-α, IL-6, and I-L1β but not BDNF levels. Activity of medial thalamus was enhanced after repeated noxious stimuli in CPSP animal and this enhancement could be blocked by acute TrKB-FC (an extracellular scavenger of BDNF) infusion. Medial thalamic spontaneous oscillatory activities could be suppressed by GABAA receptor agonist in control rats but that was enhanced in CPSP rats. Compared to control group, the expression of BDNF in medial thalamus was increased in CPSP. But expressions of GABAA channel and KCC2 channel were decreased in CPSP group. Expressions of TrKB receptor and NKCC1 channel were not different between two groups.

Our results suggested that differential mechanisms involved glutamatergic and GABAergic neurotransmission were mediated by P2X7 receptor activation and BDNF over expression respectively after CPSP development. Targeting P2X7 receptors and BDNF may be bi-effectively therapeutic as a treatment for CPSP, as a pain blocker and immunosuppressant that inhibits inflammatory damage to brain tissue which will be widely beneficial for the recovery of central pain of patients suffered from stroke.

Functional changes in entorhinal-hippocampal circuits may contribute to pain-associated object recognition memory impairment

J. Chen

Institute for Biomedical Sciences of Pain, The Fourth Military Medical University, Xi'an, China

Entorhinal-hippocampal (EC-HIP) circuits are major synaptic organizations involved in episodic memory that is acquired, stored and retrieved through its auto-association network. Neurons in layer II of the entorhinal cortex send their direct projections to dentate gyrus, while the EC layer III neurons send their fibers directly to CA1, through perforant path. The EC-HIP synaptic connections have been believed to be responsible for object recognition memory (ORM) in animals. In this report, ORM test was first used to examine whether, if any, how pain can influence upon recollection of episodic memory? Then multi-electrode array recording technique and 2D-current source density imaging were used to check whether there are spatial and temporal changes in EC-HIP circuits in the hippocampal slices? Finally, the possible mechanisms underlying nociception-associated spatial and temporal changes in EC-HIP circuits were studied. Our major results are as follows: (1) rat's OBM could be impaired by both acute inflammatory pain and chronic neuropathic pain although there was a time difference in onset. (2) peripheral blockade or morphine suppression of nociceptive afferent impulses could prevent OBM from impairing in inflammatory pain model, but not in neuropathic pain model, suggesting a difference in the underlying mechanisms. (3) when checking the induction of long-term potentiation (LTP) and long-term depression (LTD) between inflammatory and neuropathic pain states, it was surprisingly shown that higher LTP induction was accompanied by lower LTD induction in inflammatory pain model, whereas, lower LTP induction was accompanied by higher LTD induction in neuropathic pain model. Moreover, spatial enlargement of EC-HIP synaptic network was commonly observed in both types of pain models. In conclusions: (1) persistent or chronic pain impairs episodic memory recollection in rats regardless of etiology; (2) spatially and temporally functional alterations of EC-HIP circuits may contribute to pain-associated object recognition memory impairment; (3) nociceptive pain enhances LTP with blocking LTD, whereas, neuropathic pain, like stress, enhances LTD with blocking LTP. This pain etiology-specific temporal plasticity in the hippocampal formation may shed new light on the brain mechanisms of pain comorbidities such as amnesia, anxiety and depression.

Maternal environment, placental phenotype and fetal growth

A.L. Fowden

Physiology, Development and Neuroscience, University of Cambridge, Cambridge, UK

Human epidemiological and experimental animal studies have shown that the pattern of intrauterine growth is an important determinant of adult physiology with impacts on health, disease risk and, ultimately, lifespan. In particular, low birth weight is associated with adult dysfunction and overt disease of the cardiovascular, metabolic and endocrine systems in human populations (1). In experimental animals, changes in adult physiological phenotype occur after intrauterine growth restriction induced by a range of sub-optimal environmental conditions such as maternal under- or over-nutrition, hypoxia overexposure to stress hormones and administration of alcohol, caffeine and nicotine (2). Even when birth weight is unaffected by these conditions, there can be abnormalities in the subsequent functioning of physiological systems that impair the responses to environmental challenges later in life. The maternal environment during pregnancy, therefore, has an important role in controlling the development of individual fetal tissues and organ systems with physiological consequences long after birth.

This epigenetic regulation of development is determined, in part, by the placenta, the primary source of the nutrients and oxygen required for intrauterine growth (2). Growth of the placenta *per se* is impaired by many of the environmental conditions known to restrict fetal growth and program adverse physiological outcomes later in life. However, the placenta is not just a passive conduit for nutrients and oxygen. It also regulates the bioavailability of hormones with direct and indirect effects on fetal growth and can adapt its transport characteristics in response to environmental signals to help maintain fetal growth, even when its own growth is restricted. Recent studies in rodents have shown that placental phenotype in late gestation is affected by natural variations in litter size and by maternal restriction of calories and/or protein, dietary composition, particularly of fat and sugar, and by overexposure to toxins, such as alcohol and caffeine, and to natural and synthetic glucocorticoids. These adaptations in placental phenotype are both morphological and functional and involve changes in the placental imprintome, nutrient transporter abundance and the intracellular signalling pathways involved in growth and nutrient sensing. They may also vary with the sex of the offspring and with gestational age at the time of the insult. Particularly when the placenta is growth restricted, there is often an increase in the relative proportion of the labyrinthine zone responsible for nutrient uptake and a thinning of the barrier between the maternal and fetal circulations, both of which will improve transplacental transfer of nutrients and oxygen. Similarly, small placentae frequently have a greater abundance of glucose and System A amino acid transporters which increases transport of these nutrients to the fetus per gram placental mass. These changes lead to a shift in maternal resource allocation in favour of fetal growth, despite poor maternal nutrient availability in certain circumstances (3).

Changes in placental transport phenotype induced by sub-optimal environmental conditions are often associated with altered expression of several imprinted genes known to regulate placental development such *Igf2, H19, Grb10* and *Phlda2*. Indeed, deletion of these genes causes alterations in placental nutrient transport and, in some instances, abolishes the adaptive response of the placenta to environmental challenges like undernutrition. In addition, there are changes in placental expression of proteins in the PI3K, MAPK and mTOR signalling pathways in response to maternal under- and over-nutrition and to deletion of the *Igf2P0* transcript which suggests that that these pathways have a central role in mediating the effects of nutrient availability on placental phenotype. Comparison of the different genetically and environmentally induced placental phenotypes has led to the concept that the placenta may respond to fetal demand signals for nutrients, particularly when there is a mismatch between the fetal drive for growth and the materno-placental ability to supply the required nutrients. Thus, the environmentally induced changes in placental phenotype are likely to reflect a combination of signals arising from the nutritional status of the mother and fetus and from the ensuing degree of feto-placental compromise. By altering the amount and relative proportions of specific nutrients supplied to the fetus, these changes in placental phenotype can program development long after the original insult with adverse physiological consequences later in life (2,3).

An integrated approach to amino acid transfer and its regulation

J.K. Cleal

Institute of Developmental Sciences, University of Southampton, Southampton, UK

Amino acid transfer across the placenta is an important determinant of fetal growth and fetal growth restriction is associated with impaired amino acid transport.

Transfer of amino acids across the placenta requires transport of amino acids across the apical microvillous (MVM) and basal (BM) membranes of the placental syncytiotrophoblast. Individual amino acids are transported across membranes by specific amino acid transport proteins. However for the placenta to take up all the different amino acids it requires and to transfer them to the fetus it requires interaction between different classes of amino acid transporter. On the MVM accumulative transporters and exchangers must interact to mediate uptake of all the amino acids required by the placenta. On the basal membrane amino acid exchangers must interact with facilitated transporters to transfer amino acids into the fetal circulation. The interaction between different amino acid transporters creates complex interdependencies which mean that it is not easy to predict how changes in one amino acid transporter will affect the activity of the system as a whole.
Amino acid transporters can be regulated by a range of maternal signals including plasma nutrients and hormones. Within the placenta these signals are mediated via intracellular signaling mechanisms such as mTOR or by epigenetic regulation such as DNA methylation and microRNAs. The activity of amino acid transporters may be regulated by multiple regulatory signals. An important area of research is to determine whether transporters are regulated coordinately or whether they are regulated independently within the placenta.
Understanding amino acid transfer and its regulation will therefore require an integrated approach not only to the mechanisms mediating the transport but also to multiple regulatory signals which determine the activity of amino acid transporters.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Maternal obesity and placental function

T. Powell, S. Lager, I. Aye, F. Gaccioli, R. Fredrick and T. Jansson

Obstetrics and Gynecology, University of Texas Health Science Center San Antonio, San Antonio, TX, USA

Nearly two-thirds of American women enter pregnancy overweight or obese and the prevalence of maternal overweight and obesity is increasing rapidly in many other countries, including the UK. The obese mother is at higher risk for many pregnancy complications and fetal overgrowth is common in these pregnancies. Fetal overgrowth increases the risk for perinatal complications and predisposes the child for obesity, diabetes and hypertension later in life. The mechanisms underlying increased fetal growth in overweight and obese women are poorly understood. Since fetal growth largely depends on the transfer of nutrients across the placenta, we hypothesize that altered placental function in obese women may lead to fetal overgrowth and its' associated long term health consequences. We are exploring the role of altered maternal metabolism associated with obesity in regulating placental nutrient transport. The placenta, uniquely juxtapositioned between the maternal and fetal blood supplies, must integrate both maternal supply and fetal demand signals. In cases of maternal obesity the signals impinging on the placenta are diverse and include high levels of macronutrients (glucose, amino acids, fatty acids), hyperinsulinemia, elevated adipokines (leptin, TNF-alpha, IL1-beta) and low levels of adiponectin. We evaluated alterations in placental nutrient transport capacity and multiple placental signaling pathways including 1) Toll Like Receptor 4 (TLR4), 2) insulin/IGF-I 3) mammalian target of rapamycin and 4) PPARs in term placentas from women of varying pre-pregnant body mass index (BMI). We found mTOR and inflammasome pathway activation, decreased PPARgamma activation and increased expression of amino acid and fatty acid transporters in placentas of high BMI women. Additionally, we developed a model of obesity without diabetes in mice based on feeding a highly palatable high-fat and high-sugar diet. The maternal metabolic phenotype resembles that of obese women with increased leptin and decreased adiponectin. Our model results in increased fetal growth and the placentas of obese mice were found to have an activation of insulin/IGF-I and mTOR signaling and a greater nutrient transport capacity.
We used cultured primary human trophoblast cells to directly study regulation of placental nutrient transporters and demonstrated that saturated and monounsaturated fatty acids stimulate trophoblast System A amino acid uptake in a TLR4 dependent manner while omega3 long chain polyunsaturated fatty acids inhibit amino acid uptake by System A. Insulin, leptin and pro-inflammatory cytokines also increased trophoblast amino acid uptake. These data suggest that in obese mothers with high leptin, insulin resistance, and chronic pro-inflammatory activation, the placenta is stimulated by the maternal metabolic environment to deliver excess nutrients to the fetus. Adiponectin is insulin sensitizing in some tissues however elevated adiponectin, a feature of lean women, inhibits placental insulin signaling at the level of IRS-1 in cultured trophoblast cells. This would tend to decrease amino acid uptake in normal healthy pregnancies. In contrast, low adiponectin, which is associated with obesity, would promote insulin stimulated amino acid transfer across the placenta. Our experiments in cultured trophoblast cells indicate that adiponectin treatment leads to PPARalpha and p38 MAPK activation and increased ceramide biosynthesis, resulting in decreased insulin sensitivity. Additionally, we performed chronic infusion of full-length adipoenctin in normal mice and found an inhibition of placental insulin/IGF-I and mTOR signaling along with decreased fetal growth (-20%).
These studies have identified mechanistic links between the perturbed maternal metabolism in pregnancies complicated by obesity and changes in placental signaling and nutrient transport capacity that likely lead to increased nutrient delivery to the fetus. We have discovered that adiponectin constitutes an endocrine link between maternal adipose tissue and placental function, supporting our hypothesis that the maternal metabolic environment is of key importance in regulating placental function. The role of the placenta in integrating signals from both the mother and fetus involves a complex interaction of extrinsic signals such as hormones, cytokines, maternal nutrient and energy levels with intrinsic placental signaling pathways for nutrient sensing, inflammation, and growth. Understanding the complex placental signaling pathways that lead to alterations in fetal growth will allow for the development of strategies to prevent short- and long-term health consequences of pathological fetal growth.

Targeted delivery of drugs to the placenta to improve treatment of pregnancy pathologies

L.K. Harris

Maternal and Fetal Health Research Centre, University of Manchester, Manchester, UK

More than ten percent of pregnant women develop serious complications such as pre-eclampsia and fetal growth restriction (FGR), which cause significant morbidity and mortality. Despite the ability to identify women at risk of these conditions and detect reduced fetal growth and impaired utero-placental blood flow mid gestation, current treatment options are limited to induction of labour, early delivery and neonatal intensive care. In the short term, affected infants are at high risk of developing respiratory distress syndrome, retinopathy of prematurity, cerebral palsy and infection. Moreover, small size at birth is associated with an increased risk of elevated serum cholesterol, cardiovascular disease, stroke, type II diabetes, adiposity and osteoporosis in later life.
The primary causes of pre-eclampsia and FGR are poor placental growth or impaired placental function. Several potential therapies that enhance placental function, alleviate maternal symptoms and improve fetal growth in animal models have recently been identified; however, drug trials in human pregnancy are rare because the pharmaceutical industry fears expensive lawsuits associated with adverse side effects and teratogenicity. To address this issue, we have developed novel nanocarriers for targeted delivery of drugs to the placenta, as a means of improving drug efficacy and minimizing side effects in maternal and fetal tissues. We have identified a series of "placental homing peptides" which when intravenously injected, selectively bind to the uterine spiral arteries and surface of the mouse placenta, but do not bind to the vascular beds of other organs. These peptides also bind to, and are retained within, the outer syncytial layer of human placental tissue cultured in vitro. To create biocompatible nanoparticles into which drugs can be packaged, we have synthesized liposomes that display placental homing peptides on their surface. The principles of targeted drug delivery, the design and validation of peptide-decorated liposomes and the potential for this technology improve treatment strategies for pregnancy complications will be discussed.

SA194

Diabetes mellitus and the placenta: The key role of maternal and fetal insulin

G. Desoye

Obstetrics and Gynaecology, Medical University of Graz, Graz, Austria

Owing to its position the placenta is exposed to metabolic and hormonal diabetes-associated derangements of both mother and fetus, and one can expect some impact of the diabetic intrauterine environment on the placenta. One of its key functions is to provide the developing fetus with an adequate amount of nutrients, which are derived from the mother. This transport across the placenta has to be carefully regulated, because over- and undersupply may result in fetal growth disturbances. The fetus and newborn of diabetic pregnancies are characterized by excessive fat accumulation independent of the birth weight and the fetal fat associates with childhood obesity thus contributing to the obesity epidemic. Understanding the role of the maternal-placental-fetal interactions in determining fat accumulation in the fetus may thus have important implications for health care systems and the society at large.
According to the Pedersen hypothesis maternal hyperglycaemia leads to fetal hyperglycaemia with ensuing fetal hyperinsulinism. Collective evidence suggests that placental glucose transport is flow limited, and changes at the transporter level, if at all, will not affect fetal glucose levels in maternal diabetes. Thus, maternal-to-fetal glucose flux is determined by the maternal-fetal glucose concentration gradient, which itself is also regulated by fetal insulin. Fetal insulin is a main driver for fetal fat deposition, and also correlates with the risk for childhood obesity. Because of the high density of insulin receptors on the placental villous endothelium in the third trimester of pregnancy, fetal hyperinsulinism regulates some processes also in the placenta such as glycogen deposition and vascularization of the villi, both altered in maternal diabetes.
Diabetes mellitus is often associated with maternal hyperinsulinism either because of beta-cell compensation of insulin resistance or because of insulin administration to the mother. Early in gestation insulin receptors are located primarily on the microvillous membrane of the syncytiotrophoblast. Maternal insulin may then stimulate trophoblast proliferation and thereby drive placental growth. Moroever, insulin also stimulates matrixmetalloproteinases, which are implicated in extracellular matrix degrading, villous remodelling and angiogenesis. Thus, hyperglycaemia-associated maternal hyperinsulinism will modify placental growth and development in this critical period of gestation and thus have long lasting effects also on fetal development. Associations of maternal hyperglycaemia in the first trimester of pregnancy with fetal birth weight support this concept. Therefore, the main therapeutic goal in pre-gestational and gestational diabetes must be to avoid hyperinsulinism from occurring in both mother and fetus.

Effects of muscle fatigue and exercise on the way in which the nervous system drives the muscles during voluntary contractions

J.L. Taylor

Neuroscience Research Australia, Sydney, NSW, Australia and University of New South Wales, Sydney, NSW, Australia

Sustained or repetitive use of skeletal muscles leads to muscle fatigue. For human exercise, muscle fatigue can be defined as a decrease in maximal voluntary force or power of a muscle or muscle group. This definition implies that not just the muscle itself but also the nervous system has a role in exercise-related fatigue. During fatiguing exercise, the central nervous system can compensate for some weakness and slowness of the muscle to allow continued performance of a task, but

may also become "fatigued" and contribute to a fall in maximal voluntary force.

Twitch interpolation has been used to demonstrate central fatigue by showing that fatigue increases the increment in force evoked by electrical stimulation of a muscle during the performance of a maximal voluntary contraction. This interpretation has been challenged by studies in mouse muscle fibres (Place *et al.* 2008). These studies suggested that changes in the intracellular force-Ca^{2+} relationship could provide a peripheral mechanism by which interpolated twitches could grow in size with fatigue. However, interpolated twitches do not grow in human adductor pollicis when the muscle is fatigued by a sustained contraction evoked by constant frequency stimulation of the ulnar nerve (Gandevia *et al.* 2013). Rather, the twitches diminish, in part because of failure of the muscle fibre action potential. Therefore, at least for sustained maximal efforts, growth of the interpolated twitch can only occur with a reduction in neural drive to the muscle and so reflects a central component of fatigue.

The motoneurones are one site at which central fatigue may impair motor output. Our recent studies have shown that the responses of motoneurones to single corticospinal volleys are reduced during fatiguing maximal and submaximal isometric contractions (McNeil *et al.* 2009, 2011a). The reduction was most pronounced when descending voluntary drive was transiently interrupted but some reduction was also seen when voluntary drive was ongoing. These changes are unlikely to be the result of altered muscle spindle or small-diameter muscle afferent feedback (McNeil *et al.* 2011b). Furthermore, during submaximal contractions, smaller responses were more affected than larger responses. This differential effect suggests that not all of the motoneurones in the pool become less responsive but that it is mainly the motoneurones that are active during the contraction. The altered input-output relationship of the motoneurones may contribute to the mismatch between perceived effort and the level of voluntary EMG that occurs during sustained submaximal efforts.

The firing of small-diameter muscle afferents is perceived as muscle pain and/or fatigue and causes reflex cardiorespiratory responses to exercise. For the elbow flexor muscles, the ability of subjects to drive the muscle maximally in isometric maximal voluntary efforts remains low after a fatiguing contraction if the firing of fatigue-sensitive muscle afferents is maintained by block of blood flow to the fatigued muscle. Thus, these afferents contribute to central fatigue. However, this influence appears to be at a supraspinal level (Gandevia *et al.* 1996). Indeed, the motoneurones of the elbow flexors are facilitated by the afferent firing (Martin *et al.* 2006). Recent experiments have shown that the supraspinal influence of small-diameter afferent firing is not confined to the fatigued muscle. Block of blood flow to the elbow extensor muscles when they were fatigued resulted in impaired voluntary drive to the non-fatigued elbow flexors, as did maintained firing of small-diameter muscle afferents from the hand. Therefore, afferent feedback from fatigue of one muscle in a limb can alter drive to other muscles in the same limb. This is likely to be important in the development of central fatigue in most coordinated actions.

Multiple mechanisms at multiple levels of the nervous system contribute to central fatigue. They include repetitive activity, which creates a specific deficit at the motoneurone level, and sensory feedback from fatigued muscles, which has wider effects on the motoneurones and supraspinally, as well as on autonomic responses to exercise.

A model of motoneuron behavior and muscle-force generation for sustained isometric contractions

P. Contessa[1,2] and C.J. De Luca[1,3]

[1]NeuroMuscular Research Center, Boston University, Boston, MA, USA, [2]Department of Information Engineering, University of Padova, Padova, Italy and [3]Department of Electrical and Computer Engineering, University of Padova, Boston University, MA, USA

The control of motor units and the regulation of muscle force during sustained isometric contractions are still subject to debate. We have developed a model to simulate the behavior of motoneurons and the generation of muscle force in the first dorsal interosseous (FDI) and vastus lateralis (VL) muscles. The model sheds light on the mechanisms of muscle force regulation during isometric tracking tasks sustained to the endurance limit, on the changes in motor unit firing behavior and on the cause of increased force fluctuation with fatigue.

The input to the model consists of an excitatory signal representing the sum of all excitatory and inhibitory inputs to the muscle. The input excitation is common to all the motor units in the pool of the muscle following the "common drive" concept, which states that all motor units are modulated by a common source [1]. The model describes a non-linear relation between the input excitation to the motoneuron pool and the firing rates of motor units [2], to which synaptic noise is added [3]. Motor unit firing rates follow the "onion skin" principle [4], which describes a hierarchical relationship between recruitment threshold and firing rates, with later-recruited motor units having progressively lower firing rates than earlier-recruited motor units. The model generates the motor unit mechanical responses (force twitches) [5], whose amplitude is altered with contraction time to replicate the initial increase (as a result of muscle potentiation) and subsequent decrease (as a result of muscle fatigue) in force generating capacity reported during sustained muscle activation [6-7]. The force contributions of the active motor units are computed by convolving each motor unit firing train with their respective force twitch, and are summed to obtain the simulated muscle force. A feedback loop adjusts the value of the input excitation so that the simulated muscle force is maintained at a value similar to that of a target force, mimicking the performance of force-tracking tasks.

We modeled the force produced by the FDI and VL muscles during a series of repeated force contractions sustained at 50% and 20% MVC until the endurance limit, i.e., until the force could no longer be maintained at the target level. The model behavior was validated by comparing the simulated motor unit firing rate and force output with experimental evidences derived from a similar protocol of repeated contractions [6-7]. For both muscles, the model predicts the initial decrease and

subsequent increase in motor unit firing rates which occur during sustained muscle activation as motor unit force twitches vary. A greater number of motor units are progressively activated as the simulation approaches the endurance limit. Increasing force fluctuations are observed as fatigue develops, likely due to the recruitment of higher-threshold higher-twitch amplitude motor units. Throughout the contraction series, the force produced by the VL muscle is smoother than that produced by the FDI muscle, probably due to the different mechanical characteristics of the two muscles.
The results of the simulations reproduce the motor unit firing rate behavior and the increase in force fluctuations observed in previous empirical data during a similar protocol of repeated contractions [6-7]. Motor unit twitch force is the only parameter allowed to change with contraction time in the model. These results strongly suggest that, during voluntary isometric contractions, the excitation to the motoneuron pool is adjusted to compensate for the varying muscle-force generating capacity.

What experiments with intact single muscle fibres tell us about the role of calcium in muscle fatigue in mammalian skeletal muscle

J. Bruton

Physiology & Pharmacology, Karolinska Institute, Stockholm, Sweden

In humans and other mammals extended bouts of dynamic or isometric exercise result in a failure to produce the force that was possible at the start of the exercise (i.e. fatigue). Experimental results from non-invasive measurements in exercising human subjects clearly indicate that mechanisms located within the muscle are important determinants of fatigue. But it is difficult to follow the dynamics of fatigue in intact human muscle fibres *in vivo*. Muscle biopsies, NMR recordings and blood samples obtained during exercise have identified factors that potentially affect contractile function. These factors have been subsequently studied in isolated single intact fibres to determine how they affect force production and the likely mechanisms. Overall, these experiments indicate that increased inorganic phosphate and possibly ROS depress contractions resulting in fatigue, whereas increased extracellular [K^+] and reduced intracellular pH are less important. This overview uses data from isolated intact single muscle fibres from both rodents and humans to illustrate and explain the mechanisms underlying the changes in intracellular calcium and the decreased force production seen during various types of exhaustive exercise.

Weaving laboratory data into true stories from patients and their families

T. Macknight

ADInstruments, Dunedin, New Zealand

The majority of students coming into Physiology programs are doing so because they are curious about how the human body works in health and in disease, so it makes sense to build your curriculum around people and their stories. But what worries us all, is that this can sound like a plan to dilute the essential basic sciences and result in a course that is high in 'good intentions' but low in rigor. But this needn't be so. Used properly, case-based teaching can motivate students, encourage self-directed learning and enhance knowledge and understanding of basic physiological concepts.
Most courses where cases are used rely on paper cases. Here is a tyical example:
"Mrs M is a 74 year old lady who has become increasingly breathless over a number of years. She is now very limited in what she can do because of this. She was admitted to hospital with acute respiratory symptoms on three occasions over the last two years. She has a past history of cigarette smoking. On examination, Mrs M is a rather thin woman. Her face is a dusky color, and her lips have a bluish tinge. Her breathing is quiet but labored. Her chest movements are poor but symmetrical with a lot of activity in her accessory inspiratory muscles and expiratory effort as well. Listening to her chest reveals very quiet breath sounds. There are occasional crepitations and scattered rhonchi. Her heart rate is 82 bpm. Her heart sounds are normal."
The difficulty with paper cases is that we don't see the people as 'real'. The students always think that we have 'created' the person to provide a good example of the condition that we wish them to understand the basic physiology of. And certainly, with a paper case, there is a temptation to manipulate the story and the data to remove the complexities of real life. And, because the students don't really see the 'patient' as a person, they are not really concerned for him or her.
With modern computers and fast internet, it is now possible to replace these paper cases with videos. To make compelling videos what we need are co-operative patients. But we also need to be sure that the videos that we produce are of professional quality, for the students watch professional videos every day and are never happy to see 'amateur' efforts. My experience is that the most difficult part of the production is sound recording. But lighting is another problem at times. Most importantly, the format of the videos needs to be considered. Should these be filmed as interviews or should the patient speak directly to the audience? The latter seems to be the more effective in involving students in the patients and their problems.
It is also appropriate to video interviews with family and with health care professionals (doctors, nurses, physiotherapists,

occupational therapists, dieticians, etc) involved with the patient. These interviews provide students with a broader perspective about the patient's problems and their professional management.
Video cases can be used to illustrate points during lectures, as part of case-based tutorials, to reinforce laboratory work and also as part of on-line learning. They are very effective used as an introduction to the study of a new topic, for they can arouse interest in the topic and provide motivation to study it. They are also very suitable for use in group work where you wish to encourage student collaboration. During the talk, I shall provide several examples of video cases and how they can be used to motivate students, increase the relevance of laboratory time and reinforce the understanding of basic physiological concepts.

These video cases would not be possible without the informed consent of the patients to have their stories used to enhance the education of health and life science students throughout the world. We are grateful for the assistance and contributions of staff of the University of Otago School of Medicine and the Southern District Health Board.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Anecdotes in the learning of physiology

A.P. Arikawe

Department of Physiology, College of Medicine of the University of Lagos, Lagos, Lagos, Nigeria

Anecdote is a short narrative account of an amusing, unusual, revealing, and interesting event about a real incident or a person. A good anecdote must have a single and definite point. Its setting, dialogue, and characters must usually be subordinate to the point of the story. Uses of anecdotes include clarify abstract points, humanize individuals and to create a memorable image in the reader's mind.
Rudy Roden was a 17-year old medical student in Eastern Europe when the Germans invaded. He and his family were detained and sent to a concentration camp. When asked his occupation, Rudy said, "I'm a baker," and he was sent to work in the kitchens. When he was transferred to a new camp, he noticed construction going on, so he said he was a bricklayer. Rudy survived 4 different camps by being observant and making himself into whatever was needed.
After liberation from Auschwitz, Rudy Roden immigrated to Canada and became first a family physician, then a psychiatrist. Lesson from Rudy's life: if you want to survive, you have to take an active role in your future. Look around and see what is needed, what needs to be done and then figure out how you can be the one to fill that need. As Physiology educators we need to adapt and evolve. We must teach students how to do this.
During my third year Physiology undergraduate Practical session, the technical staff and students struggled for over 2 hours to anaesthetize a dog for animal experiment. A Professor of Physiology from a neighbouring institution walked into the laboratory at this point (coincidence), offered to assist and within few minutes the animal (dog) was fully sedated and unconscious! For most of the students, this was magic at the highest level
As the Physiology professor walked out of our Laboratory in Lagos 15 years ago, I quietly made a promise to work under him for MSc and PhD degrees. These were achieved in 2003 and 2012 respectively. In between these years (2008), I got the MB.BS degree! As Physiology educators we must inspire, encourage and assist our students to seek graduate admission.

Enlivening physiology teaching with African folklore

F.B. Mojiminiyi

Physiology, Usman Danfodio University, Sokoto, Nigeria

African folklore is awash with tales and proverbs e.t.c. about everyday living in Africa. These are used to teach morals and principles. Each tale or proverb is indelibly associated with a moral or principle which is easily recalled once the former is recounted. This suggests that the power of stories/proverbs in teaching is well recognized by our forbears. Folklores elsewhere share these attributes. A classical example is the so called Ondine's curse in German mythology. This tale may be used to teach the separation of voluntary from involuntary respiration (1). In addition, the National Institutes of Health (NIH) of the United States of America has been reported to have hired a professional story teller to help teach her scientists on how best to explain their research findings to others especially students and the general public. Thus the power of tales/proverbs in enhancing teaching is becoming more recognized. However this tool has either not been used at all or rarely used in the teaching of Physiology to African students. This work will present the use of African folklore in teaching physiological principles including righting reflexes, ageing, respiratory adjustments to high altitude and other aspects of physiology. This may hopefully stimulate others to explore this powerful tool in teaching physiology or communicating their research findings to colleagues, students and the public.

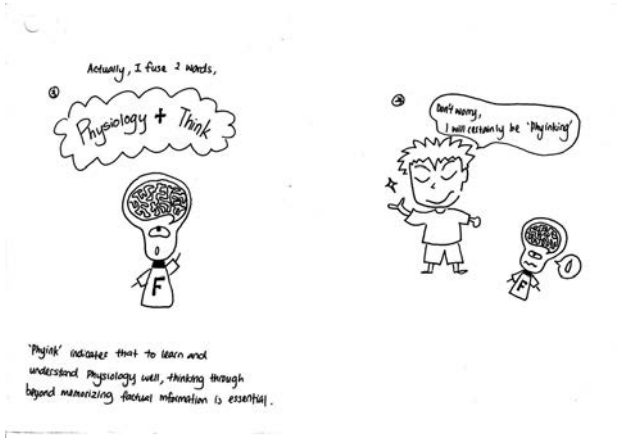
A narrative of the Facebook-PhysBook learning community

H.M. Cheng

Physiology, University of Malaya, Kuala Lumpur, Malaysia

Engaging and connecting with students learning Physiology is a primary focus of all Physiology educators. A Facebook open group was started in 2011 (PhysBook011) to exploit the ver-

satility of this social media to foster interactions, discussions and enjoyment in learning Physiology. The PhysBook group now numbers about 1,400 members, mainly students and several educators. The platform has been used for Physiology updates, Quizzes, Test sample analyses, Learning aids, Creative Physio-songs and is also open for students to pose questions and think through Physiology together. A description of some of these PhysBook learning components will be shown during this IUPS teaching enhancement session.



Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Using everyday situations to teach integrative physiology

P. Hansen

Memorial University of Newfoundland, Blaketown, NF, Canada

Research on learning and teaching has shown that learning is often more enjoyable, memorable, and meaningful when knowledge and concepts are organized around descriptions of human situations familiar to students. The evidence for this is clear and compelling, yet many physiologists are unaware of its potential for improving their students' learning. Narratives familiar to students from their everyday lives pique their interest in physiology and allow them to relate their new knowledge to what they already know. Skiing at high altitude, jogging, donating blood, having sex, and experiencing jet lag are some examples of familiar situations students can relate to. Such stories can be designed to reflect specific cultures, and to place physiology in the context of other biological sciences, social sciences, and ethics. Some situations can lead naturally to pathophysiology and clinical conditions. For example, the physiology of eating a meal is a foundation for learning about nutrition, obesity, and diabetes. Normal sexual function and pregnancy could lead to study of erectile dysfunction or infertility. This talk will articulate the theoretical and research background for using everyday stories and provide examples of their successful use in undergraduate, graduate, and health professional physiology education.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

An inhibitory connectome controls the respiratory rhythm in vivo

D.W. Richter

Neuro- and Sensory Physiology, University of Goettingen, Goettingen, Germany and Molecular Physiology of the Brain, DFG Research Center, Goettingen, Germany

The neuronal network controlling breathing under in vivo conditions is a distributed throughout the lower brainstem and the pons. Responsible for the respiratory rhythm generation is a core micro-circuitry formed within the pre-Bötzinger Complex (pre-BötC) and the Bötzinger complex (BötC) regions. A basic process is executed by glycinergic neurons forming a distinct inhibitory connectome between early-inspiratory, post-inspiratory and also late-expiratory neurons. It generates an effective control of endogenous bursting activity and allows a dynamic adjustment of breathing to behavioral and cortical commands. Disturbances of this neural management may become dangerously life threatening as they can lead to an abnormally prolonged inspiration (apneusis) producing enduring breath-holdings and also to complete cessation of breathing (apnea). Comparable defects of glycinergic inhibition were identified in several diseases, such as in Rett Syndrome, Hyperekplexia, Olivo-ponto-cerebellar atrophy (OPCA) and also Brainstem infarction.
The systemic processes underlying such disorder of respiratory activity will be explained by a comparative analysis of the effects of modulation or depression of glycinergic inhibition on single cell responses and computational modeling of complex network reactions.

Supported by the Cluster of Excellence and DFG Research Center Nanoscale Microscopy and Molecular Physiology of the Brain (CNMPB).

Purinergic modulation of preBötzinger complex inspiratory rhythm generating networks

J. Zwicker[1], S. Pagliardini[1], V. Rajani[1], S. Kasparov[2], A. Gourine[3] and G. Funk[1]

[1]Physiology, University of Alberta, Edmonton, AB, Canada, [2]Physiology and Pharmacology, University of Bristol, Bristol, UK and [3]Neuroscience, Physiology and Pharmacology, University College London, London, UK

ATP actions on central inspiratory networks are determined by a 3-part signaling system comprising: i) the excitatory actions of ATP at P2 receptors (Rs) ii) ectonucleotidases that degrade ATP into ADP and adenosine (ADO), and iii) the inhibitory actions of ADO at P1Rs. During hypoxia, an initial increase in ventilation is followed by a secondary depression that is life threatening in premature infants. The release of ATP in respiratory networks, including the preBötzinger Complex (preBötC, important site of inspiratory rhythm generation) attenuates this secondary ventilatory depression. The degree of this attenuation, however, will be determined in part by the complement and density of local ectonucleotidases. Degra-

dation of ATP to ADP, a P2YR agonist, could enhance the attenuation while degradation to ADO by different enzymes could exacerbate the depression. My thesis research has explored the significance of this 3-part signaling system for preBötC networks in rodents using primary cultures of preBötC glia, rhythmically-active medullary slices from rats and mice, and anesthetized adult rats. My objective is to use these various reduced preparations to understand the mechanisms by which ATP acts when it is released endogenously within the preBötC. In rhythmic medullary slices from neonatal rats in vitro, injection of ATP into the preBötC evokes a 2-4 fold increase in frequency via a P2Y1R mechanism that involves both neurons and glia. Analysis of cultured preBötC astrocytes suggests that the glial mechanism is mediated through phospholipase C, the release of Ca2+ from intracellular stores and the release of excitatory gliotransmitters, including glutamate, that in turn excite inspiratory neurons. In contrast to rats, however, injection of ATP into the preBötC of rhythmic slices from neonatal mice has no effect on rhythm. However, ATP does evoke a P2Y1R-mediated frequency increase if A1 ADORs are blocked, suggesting that in mice ATP is rapidly broken down into ADO, which acts via A1 ADORs to counteract the excitatory actions of ATP at P2Y1Rs. Consistent with this, ADO inhibits preBötC frequency in mice but not rats. To assess whether differential expression of ectonucleotidases might also contribute to the varied ATP responses in rats vs mice, we analyzed mRNA from preBötC punches using real time PCR to reveal that TNAP, an enzyme that degrades ATP to ADO, is the main ectonucleotidase in mice but NTPDase2, which degrades ATP to ADP (a P2Y1R agonist) is the main ectonucleotidase in rats.

The significance of these purinergic signaling mechanisms for mature preBötC networks in vivo was examined in three ways. First, injection of a P2Y1R agonist into the preBötC of urethane anesthetized rats evoked a 40% increase in respiratory frequency. Second, comparing hypoxic ventilatory responses of urethane anesthetized rats revealed that compared to control saline injections, the hypoxic ventilatory depression was much greater following unilateral injection of a P2Y1R antagonist into the preBötC. Finally, the importance of endogenous ATP in establishing the dynamics of the hypoxic ventilatory response was examined by increasing ectonucleotidase activity in the preBötC via local injection of a lentivirus that caused increased expression of the enzyme TMPAP. Compared to rats injected with a control virus, TMPAP-injected animals with elevated ectonucleotidase activity showed a much greater secondary hypoxic ventilatory depression.

Data indicate that the effects of ATP on the preBötC network of neonatal rodents are determined by a delicate balance between the excitatory actions of ATP and ADP at P2Rs and the inhibitory actions of P1R actions (on neurons and glia), and that the local subtype and concentration of ectonucleotidase is a key factor in setting this balance. In neonatal rat, the balance favours excitation. In mouse, (at least under conditions of exogenous ATP application) the excitatory actions of ATP and inhibitory actions of ADO are balanced, providing a valuable model to explore how purinergic signaling might be manipulated to tip the balance in favour of excitation to counteract respiratory instabilities as seen in apnea of prematurity. The same appears to apply to adult preBötC networks under conditions of endogenous ATP release during hypoxia where disruption the balance by increasing ectonucleotidase expression significantly alters response dynamics.

Role of synaptic inhibition for respiratory rhythm and pattern formation

A.P. Abdala[1], J.M. Bissonnette[2], J.C. Smith[3] and J.F. Paton[1]

[1]School of Physiology and Pharmacology, University of Bristol, Bristol, Avon, UK, [2]Ob/Gyn & Cell & Develop Biol, Oregon Health and Science University, Portland, OR, USA and [3]Cellular and Systems Neurobiology Section, National Institute of Neurological Disorders and Stroke (NINDS), National Institutes of Health (NIH), Bethesda, MD, USA

The current accepted model for respiratory rhythm and pattern formation dictates that a medullary inhibitory circuitry is crucial for normal breathing; however this topic is still an area of great contention. We demonstrated that the mechanisms essential for breathing combine both intrinsic cellular properties and dynamic synaptic interactions, with a major emphasis on reciprocal inhibition. With this arrangement, the central pattern generator can produce different modes of oscillatory respiratory behaviour and the circuitries pertaining to each of them can operate independently when disconnected experimentally. This not only confers the robustness and flexibility necessary for operation, but allows network reconfiguration when responding to changes in state (metabolic, arousal) or patho-physiological situations ensuring that ventilation persists. It also implies that failure in inhibitory circuitry would result in rhythm irregularity and central apnoeas. One example is the respiratory pathology featured in patients with Rett Syndrome (RTT), an autism spectrum disorder caused by mutations in the gene that encodes the DNA binding protein methyl-CpG-binding protein 2 (MeCP2). Included in the phenotype are frequent apnoeas, breathing irregularities and periodic breathing. The deficiency in MeCP2 function has been shown to affect synaptic transmission (including GABA) on multiple levels. In a mouse model of Rett syndrome, we found that insufficiency of GABAergic synaptic transmission in discrete brainstem loci was key for generating the RTT respiratory phenotype with important therapeutic implications. More recently, we generated novel viral vectors that allow us to genetically target GABAergic and glycinergic neurones providing further insight into the crucial functional role and connectivity of brainstem inhibitory neurone subpopulations. Using transgenic animals, genetic targeting of respiratory inhibitory neurones and optogenetics, I will demonstrate the essential role of synaptic inhibition within both pontine and ventral medullary respiratory regions in the generation of the eupnoeic breathing pattern.

Electrophysiological properties of the brainstem respiratory neurones in rats submitted to chronic intermittent hypoxia

D.J. Moraes

Physiology, School of Medicine of Ribeirao Preto, Ribeirao Preto, Sao Paulo, Brazil

We hypothesized that active expiration following chronic intermittent hypoxia (CIH) exposure is dependent on alterations in the electrophysiological properties of expiratory neurones in the Bötzinger Complex (BötC), in which are an important part of the complex respiratory network. Using simultaneous recordings of respiratory nerves and whole cell path-clamp of respiratory neurones of ventrolateral medulla, we evaluated the mechanisms underlining CIH-induced active expiration in juvenile rats. In CIH rats, the decrease in the frequency discharge of post-inspiratory (post-I) neurons reduced the post-I activity of cervical vagus nerve. As consequence, the firing frequency of augmenting-expiratory neurones (aug-E) and the abdominal activity in the second half expiration (active expiration) were enhanced in CIH rats. However, CIH produced changes in the input resistance and excitability, independent of synaptic transmission, only in BötC post-I neurones. These changes were due to increased potassium-mediated leak current in post-I neurones, with no changes in the currents mediated by calcium-activated large conductance potassium channels or low voltage-activated calcium channels. In addition, the increase in the potassium-mediated leak current in response to acute hypoxia (10% O2) was higher in post-I neurons from CIH than control rats. With these precise electrophysiological approaches, we are describing the mechanisms underlying active expiration in CIH rats, which critically depend on changes of ionic currents in BötC post-I neurones. Possible implications of changes in the post-I neurones electrophysiological properties in the respiratory control of upper airway resistance and in the sympathetic over activity and hypertension in CIH rats will be also discussed.

Emergence and maturation of the respiratory oscillator during embryonic development

M. Thoby-Brisson

INCIA, CNRS, Univ Bordeaux2, Bordeaux, France

Breathing is a rhythmic motor act generated and controlled by hindbrain neuronal networks. An essential component of this generator is the pre-Bötzinger oscillator that produces and paces inspiration. In order to ensure survival at birth, the respiratory generator must be anatomically and functionally established during the prenatal period. Indeed, respiratory-like movements that play an important role in the proper maturation of the lungs, respiratory motoneurons and muscles, are already present during the ultimate stages of fetal development.

Over the last decade we have sought insights into the mechanisms underlying the emergence and maturation of respiratory function during embryonic development, mainly by using electrophysiological and optical recordings of neuronal activities from reduced in vitro preparations from the mouse embryo, together with anatomical investigations. Here, I will first present some of the earlier work that has enabled 1), determining the time of inception of pre-Bötzinger circuit operation during embryonic development, 2), defining several genetic components required for the proper specification of the constitutive neuronal elements, and 3), describing some of the network properties expressed by the embryonic pre-Bötzinger oscillator. For example, we have found 1), that rhythmically organized, respiratory-related activity emerges at embryonic day 15 (E15) in the mouse (gestation lasting 18 to 19 days), 2), the homeobox gene Dbx1 is required for the specification of glutamatergic interneurons involved in respiratory rhythmogenesis, 3), intra-network synchronization relies upon glutamatergic synapses, and 4), some of the major neuronal membrane properties found at postnatal stages, including pacemaker properties, are already present before birth.

Furthermore, because respiratory-related rhythmic activity is first detectable at the beginning of the last third of gestation (E15), and since important changes have been proposed to occur elsewhere in the CNS between E15 and birth, we are currently exploring the maturational processes that the pre-Bötzinger complex undergoes during this terminal prenatal period. In this context, I will present recent preliminary data on the functional maturation of the respiratory network associated with changes both in inhibitory synaptic signaling the properties of the population of respiratory neurons exhibiting pacemaker properties.

In a translational perspective, finally, developmental anomalies in central respiratory neural control contribute significantly to human newborn mortality. Therefore, elucidating the cellular, molecular and genetic mechanisms involved in the formation and function of the respiratory generator during mammalian prenatal development is of particular importance to improving the understanding of pathologies and potentially to a better adaptation of therapeutical approaches to treating young babies suffering from respiratory distress.

Using transgenic animal models to understand the role and regulation of the gastrointestinal surface pH microclimate

U.E. Seidler

Gastroenterology, Hannover Medical School, Hannover, Germany

The gastrointestinal epithelia secrete and absorb large amounts of solvents and fluid, while being exposed to harsh conditions, such as very low pH, high CO2 tensions, food products, detergents, bacteria and their products, as well as noxious agents released by the immune cells of the organism itself. Protective properties of the gastrointestinal mucus layer have been postulated more than a decade ago, but it was clear to investigators that the mucus layer had to be traversed from the epithelium to the lumen by the very same products that it needed to be protected from, such as the gastric acid. What was actually going on directly at the epithelial surface?

Researchers from Europe, Japan and the US pioneered the study of gastrointestinal surface pH measurements more than 3 decades ago, by advancing pH- and voltage-sensitive dual-barreled electrodes through the mucus layer of chambered

isolated mucosa, and later also through the mucus of exteriorized vascularly perfused stomach of live rodents. The small intestine was probed in a similar fashion. The disadvantage was that the advancement of the microelectrode potentially disturbed the unstirred layer within the mucus. This problem was overcome two decades later, when the use of pH-sensitive fluorescent dyes and multiphoton imaging allowed dynamica monitoring of the pH immediately adjacent to the surface of the gastric mucosa. When adapting this method to other parts of the gastrointestinal tract, other pH-sensitive dyes need to be used, because of the rather small pH range within which these dyes change their emission intensities proportionally to changes in pH.

Using the above methods, it became clear that pH- gradients formed within the unstirred fluid layer in the mucus between the acidic lumen and the neutral-slightly alkaline oH of the epithelial cell layer in the upper segments of the GI tract. In the jejunum, the surface microclimate was acidic compared to the neutral lumen and enterocyte pH values. What factors allow the buildup and stability of such pH-gradients? In order to understand the regulation of the surface microclimate in a segment of the gastrointestinal tract, it has to be amenable to experimental manipulation. For the study of gastric pH gradients, acid secretion was easy to stimulate or inhibit in rodents. It was found that the stimulation of acid secretion enhanced the alkalinity of the surface pH above the mucous surface cells, possibly caused by the “alkaline tide”, the HCO3- that is exported via the parietal cell basolateral membrane and enters the capillaries that bring blood to the surface regions of the gastric epithelium. However, the opposite, the stimulation and inhibition of HCO3- secretion, was far more difficult to achieve. Thus, gene-manipulated mice were used that lacked either important transporters or important regulatory molecules for HCO3- secretion. In the stomach, this allowed the dynamic assessment of the alkaline halo adjacent to a microscopic wound and its role in protecting the wounded epithelium from acid damage. In the jejunum, changes in epithelial surface pH were found to accompany and modify the nutrient and electrolyte absorptive processes. In the colon, alterations in surface pH, brought about by deletion of the major apical Cl-/HCO3- exchanger Slc26a3 (DRA), are associated with changes in the mucus layer quality, an altered microbiome composition, an increase susceptibility to damage, and even slight inflammatory changes in the nonchallenged colonic mucosa. A combination of fluorescent markers, applied as dyes, fluorescent bacteria, or genetically expressed in the epithelial layer, allows the simultaneous assessment of tight junction integrity, mucus layer permeability, as well as of some physiological states of the cell layer below. In summary, advances in electrophysiological and imaging techniques have allowed to study dynamic changes of the surface pH microclimate during physiological digestive processes and pathological derangements. The use of transgenic animals allows, to some extent, to tentatively establish causal relationships. The development of new fluorescent markers and transgenic animal models, as well as a combination of optical and electrophysiological techniques, will likely allow an simultaneous assessment of more qualities of the surface microclimate and the underlying mucosa.

The author would like to thank her team for the many difficult experiments that allowed her to give this presentation, and the many collaborators that made knockout mice and technical knowhow available. She thanks the DFG, the Volkswagen Stiftung, the Mukoviszidose e.V. Stiftung, the Ministry of Lower Saxony, and the BMBF for financial support.

SLC26A8 and CFTR cooperation in the regulation of anions exchanges during sperm motility and activation

A. Toure

Development, Reproduction & Cancer, Institut Cochin. INSERM U1016, CNRS UMR8104, Paris, France

Ion fluxes play an essential role in the control of sperm motility and capacitation (a maturation event occurring in the female genital tract and required for fertilization); in particular, calcium, chloride and bicarbonate are essential for both processes by activating cAMP-PKA-dependent phosphorylation pathways (1). We previously described SLC26A8, also known as Testis Anion Transporter 1 (SLC26A8), as a male germ cell-specific member of a large family of anion transporters (or sulfate permeases) known as SLC26 (Solute Linked Carrier 26) proteins (2).

Most SLC26 proteins display transport activity towards monovalent and/or divalent anions (including sulfate, chloride, bicarbonate, iodide, oxalate) and in humans, genetic abnormalities of SLC26A2, SLC26A3, SLC26A4, and SLC26A, have been causally associated with diastrophic dysplasia, chloride diarrhea, Pendred syndrome and deafness respectively (3).

We have previously shown that homozygous deletion of Slc26A8 in the mouse leads to male sterility due to the total lack of sperm motility, impairment of sperm capacitation and severe structural defects of the flagellum (midpiece disorganization, hairpin-like bending of the flagellum and atrophy of the annulus). (4). Consistent with this phenotype, SLC26A8 in mature sperm localizes at the equatorial segment of the head and at the annulus, a ring shape structure at the junction between the midpiece and the principal piece of the flagellum (4).

In various epithelia, members of the SLC26 family (SLC26A3, A4, A5, A6 and A9) complex with the Cystic Fibrosis Transmembrane conductance Regulator, the chloride/bicarbonate channel mutated in cystic fibrosis, and are able to regulate CFTR transport activity (5). Interestingly, the CFTR channel has been shown to localize at the equatorial segment of the head and at the flagellum (midpiece) of mature sperm, and to be required for sperm motility and capacitation (6,7). We will report our recent findings about SLC26A8 and CFTR functional cooperation and the consequences of SLC26A8 mutations in human male fertility.

Airways surface liquid pH: regulation of ion transport by novel acid-sensitive soluble mediators

R. Tarran

University of North Carolina, Chapel Hill, NC, USA

Mucus clearance is an important aspect of the mammalian lung's innate defense system. During normal mucus clearance, inhaled pathogens become trapped in the mucus layer and are expelled before they can colonize the airways. The mucus layer is kept away from underlying epithelia by the presence of a ~7 μm periciliary liquid layer (PCL), which acts as a lubricant for the mucus. Together, these layers make up the airway surface liquid (ASL). The rate of mucociliary clearance is strongly influenced by the hydration state of the ASL. ASL volume hydration is largely maintained by Cl^- secretion through CFTR, with Na^+ and H_2O following by osmosis. However, as ASL moves up the respiratory tract, due to a reduction in surface area as airways converge, excess ASL is absorbed when needed via isotonic Na^+-led ASL absorption, which is mediated by the epithelial Na^+ channel (ENaC). Our experimental data indicate that ASL volume and ion transport regulation are in dynamic equilibrium, and that either a reduction in CFTR-mediated Cl^- secretion or an increase in ENaC-mediated Na^+ absorption will lead to ASL/PCL depletion and mucus dehydration. ENaC is highly sensitive to both membrane attached and soluble extracellular proteases which can cleave and activate ENaC. In addition, soluble volume sensing reporter molecules are present in the ASL and can bind to ENaC when ASL volume is low, removing ENaC from the plasma membrane, thus favouring secretion. These reporter molecules act as feedback sensors to modulate ASL volume. Importantly, these reporter molecules are contained within the ASL and are lost when cultures are mounted in Ussing chambers or following other experimental protocols that require flooding of the mucosal surface. The study of normal and CF airway epithelia under thin film conditions is essential to understanding the regulation of CFTR and ENaC and studies of airway epithelia under flooded conditions may produce aberrant results. In contrast, thin film studies correlate well with the increased cleavage pattern seen with ENaC in CF airways biochemically. We have recently identified the short palate lung nasal epithelial clone 1 (SPLUNC1) as one such ASL volume-sensing molecule. SPLUNC1 acts as a potent negative regulator of ENaC that serves to prevent excessive volume absorption when ASL volume is at optimum levels. Removal or dilution of SPLUNC1 leads to increased ASL absorption and temporary ENaC hyperactivity in normal airway cultures – until SPLUNC1 level rise again. For reasons that are currently under investigation, SPLUNC1 is present in CF ASL but is unable to regulate ENaC in CF airway cultures. To better understand defective SPLUNC1 regulation in CF, we identified the ENaC inhibitory domain of SPLUNC1 and further proteomic analysis suggested that this domain may be functionally deficient in CF airways in vivo. In addition to being a Cl- channel, CFTR is also permeable to bicarbonate, and CF airways are hypothesized to have a reduced ASL pH due to a lack of bicarbonate secretion through CFTR. This reduction in pH may be minimized by the backflow of bicarbonate through the paracellular pathway. Nonetheless, differences in pH in excess of 0.5 pH unit difference have been detected between normal and CF airway epithelia. In this talk, we will discuss how the interaction between soluble reporter molecules such as SPLUNC1 and ENaC are affected by pH. Furthermore, many extracellular proteases are pH-sensitive and their impact on ENaC and ASL volume will also be discussed.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Luminal pancreatic ductal acid-base microclimate and pancreatic disease

V. Venglovecz[1], Z. Rakonczay Jr.[2], J. Maléth[2] and P. Hegyi[2]

[1]Department of Pharmacology and Pharmacotherapy, University of Szeged, Szeged, Hungary and [2]First Department of Medicine, University of Szeged, Szeged, Hungary

Clinical and experimental observations suggest that acidic environment in the pancreatic lumen may increase the risk of developing acute pancreatitis. The luminal pH is mainly regulated by both acinar and ductal cells. Acinar cells secrete digestive enzymes and protons which leads to acidification in the acinar lumen (Behrendorff et al., 2010). The high proton concentration inside the lumen can distrupt intercellular junctional links which may be involved in the initiation or development of acute pancreatitis. In contrast to acinar cells, ductal cells secrete a bicarbonate-rich alkaline solution (Argent, 2006) which neutralizes the stomach acidic chyme. It has been recently highlighted that this alkaline fluid is responsible for the neutralization of the extracellular pH in the acinar lumen as well (Freedman et al., 2001). The luminal proton, secreted by acinar cells may act as a paracrine messenger on the ductal cells and stimulate ductal bicarbonate secretion via acid-sensing ion channels (ASICs) (Holzer et al., 2007). The defect in ductal bicarbonate secretion, which occurs in certain pancreatic diseases (such as cystic fibrosis) can increase the risk to pancreatitis (Hegyi et al., 2011). Recent studies on ductal cells suggest that toxic factors, such as bile acids (Venglovecz et al., 2008) or ethanol (Yamamoto et al., 2003) also inhibit pancreatic ductal bicarbonate secretion which acidifies the lumen of the ducts and slows down the washout of the digestive enzymes. In summary, characterization of the ductal acid sensing mechanisms is essential to understand the acinar-ductal functional unit and may improve our knowledge in the pathomechanism of pancreatitis.

Unraveling secreted mucins by luminal HCO_{3-} ions

J. Yang[1], G. Flores[1], A.K. Shamsuddin[1] and P.M. Quinton[1,2]

[1]Department of Pediatrics, University of California San Diego, San Diego, CA, USA and [2]Biomedical Sciences, University of California, Riverside, CA, USA

Mucus coating epithelia is one of the most critical components of innate defense against injury and infection of internal organs. To become protective, however, mucins, which are the longest, largest molecules in biology, must unravel from intensely condensed structures inside intracellular granules to occupy volumes 3 orders of magnitude larger as extracellular molecular 'mucus'. Impressively, the transformation occurs within seconds at most. Having found that the formation of "mucus' is critically dependent on the presence of HCO_{3-} (1) (2), we now address the properties of mucin / HCO_{3-} interactions and secretions. We surmise that HCO_{3-} effects mucus unraveling largely by competing away Ca2+ that divalently bridges the innumerable anionic sites fixed to the mucin peptide polymers, but other binding may also be involved. Using pH stat and transepithelial electrical measurements of HCO_{3-} flux, we show that HCO_{3-} is secreted in the intestines, airways, and reproductive tracts. Using histochemical staining of mucus (3) with morphometry, we determine relative losses of mucin from goblet cells. By applying selective inhibitors (GlyH-101, DIDS, acetazolamide) and agonists (Isoproterenol, Forskolin/IBMX, PGE2, Carbachol, UTP, VIP) in the presence and absence of HCO_{3-}, we illustrate the impact of HCO_{3-} secretion on mucin exocytosis and mucus discharge in these systems. These results indicate that secretion of gel forming mucins and HCO_{3-} secretion are regulated independently and in separate cells. It appears that exocytosis of gel forming mucins from goblet cells is largely under Ca2+ mediated control, while HCO_{3-} secretion derives from surrounding secretory cells is largely under cAMP mediated control of CFTR. Thus, even though HCO_{3-} may affect the exocytosis of mucins, the luminal secretion of HCO_{3-} appears to be required to support normal mucus maturation and formation. The relevance of these results to pathogenesis will be considered.

Homeostatic responses fail to correct defective amygdala inhibitory circuit maturation in Fragile X syndrome

M. Huntsman

Pharmaceutical Sciences and Pediatrics, University of Colorado, Aurora, CO, USA

Fragile X Syndrome (FXS) is a debilitating neurodevelopmental disorder thought to arise from disrupted synaptic communication in several key brain regions including the amygdala - a central processing center for information with emotional and social relevance. Recent studies reveal defects in both excitatory and inhibitory neurotransmission in mature amygdala circuits in Fmr1-/y mutants, the animal model of FXS. However, whether these defects are the result of altered synaptic development or simply faulty mature circuits remains unknown. Using a combination of electrophysiological and genetic approaches, we show the development of both pre- and postsynaptic components of inhibitory neurotransmission in the FXS amygdala is dynamically altered during critical stages of neural circuit formation. Surprisingly, we observe that there is a homeostatic correction of defective inhibition, which, despite transiently restoring inhibitory synaptic efficacy to levels at or beyond those of control, ultimately fails to be maintained. Using inhibitory interneuron-specific conditional knockout and rescue mice, we further reveal that Fragile X Mental Retardation Protein (FMRP) function in amygdala inhibitory microcircuits can be segregated into distinct pre- and postsynaptic components. Collectively, these studies reveal a previously unrecognized complexity of disrupted neuronal development in FXS and therefore have direct implications for establishing novel temporal and region-specific targeted therapies to ameliorate core amygdala-based behavioral symptoms.

Abnormal thalamocortical activation of somatosensory cortex in the young Fmr1-KO mouse model of Fragile X Syndrome

A. Domanski[1,2], J.T. Isaac[2,3] and P.C. Kind[1]

[1]Biomedical Sciences, University of Edinburgh, Edinburgh, Midlothian, UK, [2]NINDS, National Institutes of Health, Bethesda, MD, USA and [3]Eli Lilly and Company, Erl Wood, Surrey, UK

Fragile X Syndrome (FXS) is the most common heritable form of intellectual disability, affecting 1:4-6000 children, and a prominent genetic cause of Autism. Symptoms include cognitive impairment, seizures, and deficits in sensory processing including tactile hypersensitivity. Dissecting sensory cortical pathophysiology in FXS offers insight into both sensory dysfunction and higher cognitive impairment. Studies in the Fmr1-KO mouse model of FXS display developmental and lasting abnormalities in cortical neuronal physiology. In particular, altered plasticity at thalamocortical (TC) synapses, the principal cortical input for ascending sensory information, was shown in somatosensory cortex during the first 10 postnatal days. During this early critical period in wild-type (WT) mice, the temporal resolution of TC inputs undergoes coordinated developmental refinement to selectively promote cortical responsiveness to high frequency TC synaptic activity essential for high fidelity tactile coding and activity-dependent refinement of intracortical circuitry.

Hypothesizing that abnormal presentation of sensory inputs at the first stage of cortical processing could both affect juvenile sensory perception in FXS and impair the maturation of cortical circuits, we examined TC input responses in the juvenile Fmr1-KO somatosensory cortical Layer 4 (L4) circuit. Synaptic integration, L4 connectivity and evoked network activity were investigated using whole-cell and Multi-Electrode Array electrophysiology in a TC brain slice preparation. Relative to WTs, Fmr1-KO L4 excitatory neurons displayed elevated intrinsic excitability, increased feed-forward inhibitory drive and altered TC synaptic kinetics. Intracortical connectivity between excitatory/excitatory and excitatory/inhibitory neurons was broadly reduced in Fmr1-KOs. Computational simulations of TC input integration informed by in vitro data suggested dynamic re-tuning of TC processing in Fmr1-KOs by distributed circuit mechanisms but an uncompensated hypersensitivity to high frequency stimulation. As predicted, thalamorecipient excitatory neurons in Fmr1-KO slices showed altered temporal resolution of TC inputs following thalamic stimulation with behaviourally relevant patterns. Significantly exaggerated voltage summation could be achieved in L4 excitatory neurons following burst stimulation at 20-50Hz, with abnormal recruitment of reverberant L4 network activity possible following 5-20Hz stimulation. Quantifying L4 network activity in Fmr1-KO slices demonstrated pronounced reductions in population response sparsity, spike rate and trial-to-trial fidelity in Fmr1-KOs, with reduced spatial spread of network activity.

Together, these data demonstrate cortical hypersensitivity to TC inputs and abnormal recruitment of network activity by critical period Fmr1-KO somatosensory cortical circuits. The hyperresponsiveness and reduced fidelity of intracortical circuitry following behaviourally salient stimuli demonstrated in the present study may underlie tactile hyperexcitability and abnormal sensory discrimination in FXS patients, and likely contribute to deleterious cortical development.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA215

Altered vesicle dynamics and neuronal synchrony in a mouse model of mental retardation

A.D. Powell, P. Saintot, K.K. Gill and J.G. Jefferys

School of Clinical & Experimental Medicine, University of Birmingham, Birmingham, UK

Mental retardation (MR) is a common disorder affecting 2-3% of the general population; a leading cause of moderate to severe MR is mutations of genes located on the X-chromosome. One gene implicated in X-linked mental retardation (XLMR) is the OPHN1 (*Ophn*-1 in mice) gene which encodes oligophrenin-1, a RhoGAP protein. Loss of function mutations upregulate Rho GTPase-dependent signalling pathways leading to altered actin cytoskeleton dynamics which are important in vesicle dynamics and dendritic spine structure. In addition to its function in regulating actin dynamics, oligophrenin-1 regulates the kinetic efficiency of clathrin-mediated endocytosis of synaptic vesicles leading to reduced repetitive activation in inhibitory synapses.

As neuronal synchrony in the hippocampus plays a role in encoding and retrieving episodic memory and attention, we hypothesised that alterations in synaptic vesicle availability will alter neuronal synchronisation and could underlie the reduced cognitive performance of *Ophn*-1 null mice. *Ophn*-1 mice (male 15-30g, 3-10 weeks old) were anaesthetised by I.P. injection of medetomidine (1mg/kg) and ketamine (76mg/kg). Values are expressed as mean±S.E.M, compared by ANOVA or Student's t-test.

Initial experiments tested if oligophrenin-1 functioned as a regulator of vesicle availability in hippocampal CA3 synapses. Whole cell patch-clamp recordings from CA3c pyramidal neurons revealed that the frequency of spontaneous EPSCs and IPSCs (excitatory postsynaptic currents and inhibitory postsynaptic currents) was lower in *Ophn*-$1^{-/y}$ than *Ophn*-$1^{+/y}$ neurons (sEPSCs: 1.67±0.37 Hz, n=9; 6.91±1.50 Hz n=8, p=0.003; sIPSCs: 8.78±0.81 Hz, n=7; 12.63±0.76 n=7, p=0.009, respectively). Consistent with reduced spontaneous transmission, evoked IPSCs were significantly smaller in *Ophn*-$1^{-/y}$ neurons than *Ophn*-$1^{+/y}$ neurons (1573.3±172.5 pA, n=15 and 2316.9±278.6 pA, n=13, respectively; p=0.02).

As neuronal synchrony is dependent on the ability of inhibitory synapses to follow repetitive activation, we examined whether secretory vesicle availability was altered in *Ophn*-1 null slices at frequencies relevant to cognition. Inhibitory synapses were stimulated at 33 Hz; IPSCs built up with successive stimuli, reaching a steady level within 10 stimuli in *Ophn*-$1^{+/y}$ neurons; IPSC facilitation was much weaker in *Ophn*-$1^{-/y}$ neurons (p=0.001). We tested whether this inability to follow repetitive stimulation was a result of a reduced readily releasable pool (RRP) of synaptic vesicles. The RRP was smaller in *Ophn*-$1^{-/y}$ than *Ophn*-$1^{+/y}$ synapses (513.8±100.9 pA, n=7 and 1466.2±307.7 pA, n=5, respectively, p=0.005), corresponding to a smaller number of vesicles in the RRP (12±2 and 35±7, respectively).

Gamma oscillations can be generated *in vitro* in the CA3 region of the hippocampus by tonic activation of kainate receptor or can occur spontaneously. Spontaneous gamma activity was

smaller in *Ophn*-1$^{-/y}$ slices than in *Ophn*-1$^{+/y}$ slices (27.5±7.6 μV^2, n=8 and 66.0±13.7 μV^2, n=10, respectively, p=0.03). Superfusion of KA (50 nM) increased CA3 network activity throughout its application in both *Ophn*-1$^{+/y}$ and *Ophn*-1$^{-/y}$ slices. KA-induced gamma oscillations were significantly smaller in *Ophn*-1$^{-/y}$ slices than in *Ophn*-1$^{+/y}$ slices (2910.1±521.3 μV^2, n=21 and 5906.2±936.9 μV^2, n=30, respectively, p=0.02).

We have previously shown that the synaptic deficits in *Ophn*-1$^{-/y}$ neurons are reversed by acute inhibition of Rho-kinase (ROCK) activity. Application of the ROCK inhibitor, Y–27632 (10 μM, for 20 minutes) significantly increased spontaneous oscillations in *Ophn*-1$^{-/y}$ slices (vehicle 71.5±19.2 μV^2, Y–27632 215.8±51.8 μV^2, p=0.005). In *Ophn*-1$^{+/y}$ slices, Y–27632 did not affect spontaneous oscillations (vehicle 137.5±20.9 μV^2, Y–27632 180.8±40.9 μV^2, p=0.32).

In the present study, we investigate the role of oligophrenin-1 in neuronal network activity; particularly spontaneous- and kainate-induced gamma oscillations using the *Ophn*-1 mouse model of intellectual disability. We demonstrate that hippocampal inhibitory synapses are unable to function at frequencies necessary for higher cognitive function, due to a substantial decrease in the readily releasable pool (RRP) of synaptic vesicles. We propose that these synaptic changes underlie the deficits in gamma oscillations. The rescue of the emergent neuronal network activity by small molecule pharmacological inhibition of the downstream signalling pathway of oligophrenin-1, raises the possibility of a pharmacotherapy to treat affected individuals.

Troubled translation in Fragile X

E. Osterweil[1], S. Chuang[2], A.A. Chubykin[1], M. Sidorov[1], R. Bianchi[2], R.K. Wong[2] and M.F. Bear[1]

[1]Picower Institute for Learning and Memory, MIT, Cambridge, MA, USA and [2]The Robert F. Furchgott Center for Neural and Behavioral Science, State University of New York Downstate Medical Center, Brooklyn, NY, USA

A major single-gene cause of autism is fragile X syndrome (FXS), a developmental disorder associated with intellectual disability and a high incidence of epilepsy. FXS develops due to silencing of the *FMR1* gene and subsequent loss of FMRP, a potent repressor of translation. The long-term depression of synaptic strength (LTD) induced by metabotropic glutamate receptor 5 (mGluR5) activation is enhanced in the FXS mouse model (*Fmr1* KO), and it has been suggested that the protein synthesis downstream of mGluR5 significantly contributes to the synaptic pathophysiology of the disorder. Consistent with this, we find that hippocampal protein synthesis is excessive in the *Fmr1* KO, and that acute pharmacological inhibition of either mGluR5 or the ERK1/2 signaling pathway is sufficient to normalize protein synthesis to WT levels. This correction is specific to the ERK1/2 pathway, as inhibition of the mTOR pathway does not normalize protein synthesis in the *Fmr1* KO.

Interestingly, it had been shown that a mild reduction of ERK1/2 activity can be achieved by disrupting the post-translational maturation of the upstream activator, Ras using the HMG-CoA reductase inhibitor, lovastatin. Based on these findings, we tested the efficacy of lovastatin for correcting pathological phenotypes in the *Fmr1* KO. Remarkably, we find that lovastatin, a drug in widespread use and approved to treat hypercholesterolemia in children, decreases Ras-ERK1/2 signaling, normalizes excessive protein synthesis, corrects exaggerated hippocampal mGluR-LTD, eliminates hippocampal epileptiform activity, normalizes neocortical hyperexcitability, and significantly ameliorates audiogenic seizures (AGS) in the *Fmr1* KO mouse. These data suggest that lovastatin is potentially disease modifying, and could be a viable prophylactic treatment for FXS.

Synaptic alterations in animal models of Rett syndrome

T. Pizzorusso[1,2], E.M. Boggio[2,3], G. Della Sala[1], M. Giustetto[3], G. Lonetti[2] and E. Putignano[2]

[1]NEUROFARBA, Universty of Florence, Pisa, Italy, [2]Inst Neuroscience, CNR, Pisa, Italy and [3]Neuroscience, University of Turin, Turin, Italy

There is mounting evidence showing that the structural and molecular organization of synaptic connections is affected both in human patients and in animal models of neurological and psychiatric diseases. As a consequence of these experimental observations, it has been introduced the concept of synaptopathies, a notion describing brain disorders of synaptic function and plasticity. A close correlation between neurological diseases and synaptic abnormalities is especially relevant for those syndromes including also mental retardation in their symptomatology, such as Rett syndrome (RS). RS (MIM312750) is an X-linked dominant neurological disorder that is caused in the majority of cases by mutations in methyl-CpG-binding protein 2 (MeCP2). We will discuss recent data characterizing synaptic alterations in animal models of RS and their regulation by environmental and molecular factors.

Selected scientific topics on synthetic biology

F. Képès

institute of Systems & Synthetic Biology, Genopole®, CNRS, Evry, France

Synthetic Biology is the engineering of biology: the deliberate (re)design and construction of novel biological and biologically based systems to perform new functions for useful purposes, that draws on principles elucidated from biology and engineering (source: ERASynBio). Synthetic Biology is an emerging and promising research area with the potential to have a strong impact on future innovation and technological progress that is beneficial for the economy and for society as a whole. Synthetic Biology is at the intersection of engineering, bioscience, chemistry, and information technology. It provides concepts and toolboxes that open the way to a wide range of biotechnological applications in health, environment, bioenergy and fine chemical synthesis. It also allows to ask some fundamental questions in a new and sometimes more efficient way.
This lecture will provide a multifocal definition of Synthetic Biology and of its scientific contents. It will discuss of the epistemological conditions of its recent emergence. It will finally cover a wide ground of applications of Synthetic Biology through specific examples.

SA219

Legal knowledge gaps and constructs in synthetic biology - a comparative review of the state of the art

D. Milius

Department of Human Genetics, Faculty of Medicine, McGill University, Montreal, QC, Canada and Department of Commercial Law, Faculty of Law, University of Cape Town, Cape Town, Western Cape, South Africa

Gene systems and organisms constructed using synthetic biological techniques will have their origins in the human mind and imagination, and as such, will not be the products of nature. Though isolated and purified sequences are patentable, with recent controversies noted, they must satisfy the patentability criteria in addition to satisfying the usual statutory subject matter requirement. Should controversy over the patentability of isolated human genes persist, the value of synthetic genes to scientists will markedly rise. But even then there exist legal gaps, and with their more recently proposed solutions, the suggestion is to develop new legal constructs to adapt the law to newer modes of doing new things in biology. For instance, the implications for copyright's threefold requirement of original authorship, of enabling expression in a fixed medium, and of the work being capable of reproduction (so far narrowly understood), make it an attractive intellectual property right to consider though there are others that might also apply as scientists develop more capable "biological software". Trademarks and trade secrets are other potentially lucrative options that might be balanced by more open synthetic biology modes of production, which essentially take a non-proprietary approach to innovation in biotechnology. This presentation will include a discussion of syn-agriculture and of third-to-fourth-generation biofuels in order to help draw a map of the contours of the legal certainties, as well as to identify the perceived gaps and their current conceptual boundaries. It is hoped that evaluating the extent to which the proposed solutions address these uncertainties will help identify opportunities for the effective regulation and management of synthetic biology as a tool with the potential to improve food resources and energy production for the foreseeable bio-future.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA220

Who owns living organisms issued from synthetic biology?

C. Rhodes

University of Manchester, Manchester, UK

This presentation focuses on synthetic organisms in the sense of the biological 'parts' that are developed and the microorganisms in which they are combined in the field of synthetic biology. Starting from the basis of looking at approaches that can be taken to the ownership of genetic resources (the definition of which includes those of synthetic origin), it examines which of these approaches might be appropriate for synthetic organisms and whether the products of synthetic biology should be treated any differently from other genetic resources in this regard. Approaches that have been taken to ownership of genetic resources include: free access; common heritage; intellectual property rights; state sovereign rights; and the rights of farmers, local groups and indigenous peoples. Application of state sovereign rights and availability of intellectual property rights protection are the current dominant approaches (the latter being particularly controversial). The presentation will argue that these approaches are inappropriate on both practical and ethical grounds, and recommend a shift towards a (modified) common heritage approach to synthetic organisms (and genetic resources more generally).

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA221

Biotechnology and use of living: a public matter

D. Browaeys

VIVAGORA, Paris, France

Nanotechnology: « manipulate atoms » is a slogan which responds now to a more ambitious project: "Life manufacturing". After molecular biology permitting to spell out the genetic code and more especially analyze the genetics programs, we are now thinking about rewrite them to obtain shaped organisms. This dreaming project stimulates the imagination of all the pioneers of synthetic biology. They promise to transform the coal in methane thanks to reprogrammed bacteria, resurrect mammoths and, why not, humans... After mechanical industries and chemical industries, are we going to see a new industrial age, the age of biological machine? These promises are they credible? If it's the case, what are the dangers of these new technologies and how to control it? Is this biology really conforming to our cultural and ethical values? And is that the biology we want for our society? The bioeconomy of the 21st century aims to increase the capabilities

of energy, foods, drugs and materials productions... Synthesis biology is not simply the processing of few microbes, plants, animals in productive factories but the commoditized production of unreleased organisms with which we had to live and not without socials, economics and ecological consequences. Indeed, what happens to our judgment concerning the distinction between artificial and natural, living and inanimate? How do we control the spread of "animated tools" we build? Who take the responsibilities for these autonomous products? Today it is a necessity to think about the issues of these new technologies and explore their strengths, limitations and alternatives. Face to these questions, VivAgora has implemented since 2009 many reflections about synthesis biology through a first cycle of events and purchase this approach with a workshop scenario and a seminar called "Les Assises du Vivant" in 2012. Furthermore, Bernadette Bensaude-Vincent and Dorothée Benoit-Browaeys co-authored in 2009 the book "Fabriquer la vie: Où va la biologie de synthèse?" In 2013, VivAgora became part of the "Observatory synthetic biology" steering committee. Who is VivAgora? Vivagora is an NGO involved in organizing debates on societal issues raised by scientific and technological innovations. By promoting the expression and inclusion of all stakeholders, and exploring the diversity of their views and goals, it seeks to build trust and promote a new culture of innovation. In a world where risks and uncertainties are increasing, VivAgora want to make sure that scientific and technological development benefits the community at large. Its goals: Help citizens understand issues raised by technological developments Create opportunities for stakeholders with conflicting interests to discuss their perspectives, support dialogue between stakeholders in order to explore responsible innovation practices and facilitate the inclusion of all stakeholders in scientific and technical decision-making bodies. Competences: Since 2003, VivAgora has implemented many cycles of public debates focused on health, environment, nanotechnologies, synthetic biology, neurosciences...It has developed an extensive expertise on the analysis and elaboration of engagement processes. It has initiated a Citizen Alliance on the challenges of nanotechnologies supporting the website: http://nano.acen-cacen.org/AccueiL. VivAgora is also mobilized on pluralist expertise and its process called COEXnano is devoted on nanocoating (supported by the Ministry for environment). The NGO has developed regional activities to encourage the creation of citizens groups concerned by nanotechnologies' programs. Those groups expressed themselves within the Nanoforum meetings in Paris (supported by the Ministry of health). Stopped in 2009, the forum will come back in 2013 with several meeting focused on "accountable practises". VivAgora gathers both public and private professionals involved in scientific and technological innovation, in open innovation events. VivAgora's website [www.vivagora.fr] presents current debates and news (quarterly Vivagoveille), as well as public engagement processes in France and worldwide. Accessible to anyone, it offers a wide variety of in-depth articles, alerts on emerging issues, a calendar of public events, and VivAgora activities.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA222

Role of microRNAs in vascular inflammation and proliferation in response to mechanical stress

S. Chien

Departments of Bioengineering and Medicine, and Institute of Engineering in Medicine,, University of California San Diego, La Jolla, CA, USA

Vascular endothelial cells (ECs) play significant roles in regulating circulatory homeostasis. The shear stress resulting from circulatory flow modulates EC functions by activating mechano-sensors, signaling pathways, and gene and protein expressions. Sustained shear stress with a clear direction (e.g., the pulsatile shear stress, PS, in the straight part of the arterial tree) down-regulates the molecular signaling of pro-inflammatory and proliferative pathways. In contrast, shear stress without a definitive direction (e.g., the disturbed or oscillatory flow, OS, at branch points and other regions of complex geometry) causes sustained molecular signaling of pro-inflammatory and proliferative pathways. The EC responses to directed mechanical stimuli involve the remodeling of EC structure to minimize alterations in intracellular stress/strain and elicit adaptive changes in EC signaling in the face of sustained stimuli; these cellular events constitute a feedback control mechanism to maintain vascular homeostasis and are athero-protective. Such a feedback mechanism does not operate effectively in regions of complex geometry, where the mechanical stimuli do not have clear directions, thus placing these areas at risk for atherogenesis. The differential modulation of EC functions by various flow patterns involves intricate interplays of signaling pathways and gene regulation, with the participation of microRNA (miR). For example, miR-23b mediates the PS-induced inhibition of EC proliferation by causing RB hypophosphorylation, and miR-21 mediates the OS-induced monocyte adhesion to ECs by enhancing the expression of adhesion molecules such as vascular cell adhesion molecule-1 and monocyte chemotactic protein-1. miR-92a exerts an inhibitory effect on the transcription factor KLF2, which is anti-inflammatory and anti-proliferative. The athero-protective effect of PS is mediated by the inhibition of miR-92a and the atherogenic effect of OS is mediated by the activation of miR-92a. There is also evidence that ECs can release miR-126 to modulate the gene expression and functions of vascular smooth muscle cells via a paracrine mechanism. These experimental studies on miR, in combination with the in silico approaches in systems biology, provide new insights on the mechanism of the fine tuning of gene regulation in response to differential flow patterns in health and disease.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA223

The role of nuclear matrix on proliferation and apoptosis of vascular cells modulated by mechanical strain

Y. Qi, Y. Han and Z. Jiang

Institute of Mechanobiology & Medical Engineering, Shanghai Jiao Tong University, Shanghai, China

Background: Arterial wall is exposed to three main hemodynamic forces in vivo: shear stress, caused by the dragging fric-

tional force of blood flow; transmural pressure, caused by the hydrostatic forces of blood within the blood vessel; and cyclic strain, defined as the repetitive deformation of the cells as the arterial wall rhythmically distends and relaxes with the cardiac cycle [1]. It had been proved that pathophysiological mechanical states of vascular cells, i.e. endothelial cells (ECs) and vascular smooth muscle cells (VSMCs), contribute to vascular disorder resulting from atherosclerosis, hypertension, bypass graft occlusion, et al [1, 2]. Nucleus is the largest and stiffest organelle in the cell, where is the site of transcriptional regulation, and contains the genome [3]. Nuclear matrix acts as the skeleton structure of the nucleus, but its role in mechanosensing and gene-expression-regulating is still unclear.
Methods and Results: The co-culture parallel-plate flow chamber system was used to mimics the shear stress, and FX-4000T Strain Unit to mimics the cyclic strain, respectively. We demonstrated the effects of three kinds of nuclear matrix proteins, i.e. Nesprin2, SUN1 and LaminA, in proliferation and apoptosis of vascular cells modulated by shear stress and cyclic strain. Our results indicated that both shear stress and cyclic strain application significantly modulated the expressions of Nesprin2, SUN1 and LaminA, but in different ways. Physiological shear stress (15 dyne/cm2) and pathological shear stress (5 dyne/cm2) revealed similar repressed effect on expressions of nuclear matrix in comparison with the static control. Physiological cyclic strain (5% elongation) increased, but pathological (15% elongation) decreased the expressions of nuclear matix proteins. By using target siRNA and overexpression plasmid transfection in ECs and VSMCs respectively, it revealed that nuclear matrix proteins participated in regulation of apoptosis and proliferation. Furthermore, the activations of transcription factors were detected by Protein/DNA array after both suppressing and increasing nuclear matrix proteins expressions. TFIID, regulated by Nesprin2, Stat-1, 3, 5 and 6, regulated by LaminA, were remarkably changed in vascular cells transfected with target siRNA and overexpression plasmid respectively.
Conclusion: Our study revealed that nuclear matrix proteins might be the novel mechanical-sensitive molecules in vascular cells, which and may play a crucial role in cell functions.

Atheroprotective effects of shear stress through the regulation of the renin-angiotensin system

S. Lehoux

Lady Davis Institute, McGill University, Montreal, QC, Canada

Atherosclerosis develops primarily at arterial bifurcations or curvatures, where flow is oscillatory, whereas vascular segments exposed to shear stress are protected. We showed that local, endothelial-specific angiotensin type 1 receptor (AT1R) expression may be pathologically significant: 1) endothelial expression of AT1Rs, which transduce most known effects of AngII, localizes to low flow, plaque-prone sites in the aorta, and 2) in vitro, endothelial AT1R expression is downregulated by shear stress. Recent data has allowed us to define how shear stress regulates AT1R expression acutely, through interaction with caveolin-1 and internalization. This process is important for shear stress-dependent activation of ERK1/2. We have also found that the hemodynamic environment may influence the expression of other components of the renin-angiotensin system, pointing to a localized tissue regulation of angiotensin II release and activity. Our findings illustrate the many levels at which shear stress orchestrates vascular function.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA225

Regulation of proinflammatory signalling pathways by shear stress in vascular endothelial cells

M. Zakkar

Cardiothoracic surgery, St Georges Hospital, University of London, London, UK and Cardiovascular medicine, Imperial college, London, UK

Atherosclerosis is a chronic inflammatory disease. Several pro-inflammatory mediators
including (LPS and TNFα) activate EC by simultaneously activating dual NF-KB and MAP kinase signalling pathways. The activity of p38 and JNK MAP Kinases is tightly controlled in EC by several negative regulators including MAPK phosphatase-1 (MKP- 1) and the transcription factor Nrf2.
Blood flow exerts several mechanical forces on endothelial surfaces including pressure,
circumferential stretch, and shear stress (mechanical drag). It is widely believed that shear stress plays a central role in the pathogenesis of atherosclerosis as lesions predominate at regions exposed to disturbed flow that is associated with low shear stress while regions exposed to high shear stress are protected.
MKP-1 is a central mediator of the anti-inflammatory effects of shear stress. Studies using cultured human umbilical vein EC (HUVEC) revealed that MKP-1 is induced by prolonged high shear stress. In-vivo studies of murine aortae by en face staining showed that MKP-1 is expressed at atheroprotected sites which are exposed to high shear stress but not at atherosusceptible sites. The assessment of the functional role of MKP-1 in-vivo was carried out by comparing wild type and MKP-1-/- C57BL/6 mice which revealed that MKP-1 is necessary for the suppression of p38 and JNK activity, and VCAM-1 expression

at atheroprotected sites as the genetic deletion of MKP-1 can lead to the loss of protection at these sites.
The c-Jun N-terminal kinase (JNK) is activated constitutively in EC at atherosusceptible sites but is inactivated at atheroprotected sites. The identification of transcriptional programs regulated by JNK by applying a specific pharmacological inhibitor to cultured EC and assessing the transcriptome using microarrays and subsequent validation by gene silencing revealed that JNK positively regulates the expression of numerous proapoptotic molecules. Analysis of aortae of wild-type, JNK1(-/-), and MKP-1(-/-) mice revealed that EC at an atherosusceptible site express proapoptotic proteins and are primed for apoptosis and proliferation in response to lipopolysaccharide through a JNK1-dependent mechanism, whereas EC at a protected site expressed lower levels of proapoptotic molecules and were protected from injury by MKP-1.
Nrf2 is also essential for the suppression of endothelial activation by high shear. The activation of Nrf2 at atherosusceptible sites of murine aortae by sulforaphane (a dietary antioxidant that acts as a potent activator of Nrf2) suppressed p38 activation and VCAM-1 expression in cultured EC. In-vivo studies showed that the administration of sulforaphane increased Nrf2 activity and reduced p38 activation and VCAM-1 expression at the atherosusceptible sites of wild type but had no effect on Nrf2-/- C57BL/6 mice.

Athero-susceptibility of the stressed endothelium

P.F. Davies[1,2], M. Civelek[2,6], Y. Fang[1,7], E. Manduchi[4], P. Islam[3], Y. Zhang[5] and Y. Jiang[1]

[1]Pathology & Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, USA, [2]Bioengineering, University of Pennsylvania, Philadelphia, PA, USA, [3]Chemistry, University of Pennsylvania, Philadelphia, PA, USA, [4]Center for Bioinformatics, University of Pennsylvania, Philadelphia, PA, USA, [5]Biomedical Graduate Studies, University of Pennsylvania, Philadelphia, PA, USA, [6]Medicine, UCLA, Los Angeles, CA, USA and [7]Medicine, University of Chicago, Chicago, IL, USA

Endothelial phenotype heterogeneity plays an important role in the susceptibility of the cardiovascular system to pathogenesis. Arteries (and heart valves) are susceptible to chronic inflammatory disease in regions of blood flow disturbance, implicating hemodynamic forces and transport characteristics as prominent influences upon pro-pathological endothelial phenotype.
Our studies are focused on the normal and hypercholesterolemic domestic swine (Sus scrofa), an animal model close to human physiology and pathology, and are complemented by mechanistic in vitro studies of human arterial endothelial cells. All animal procedures were conducted under FDA and University of Pennsylvania IACUC approved protocols
Microarrays and next generation sequencing combined with systems analyses were used to identify differential expression of genes, small regulatory RNAs and epigenetic modifications in atherosusceptible endothelium. Data obtained from such high throughput 'omics' (discovery science) measurements in cells freshly harvested from the in vivo environment 'informed' the design of in vitro experiments (reductionist science). Where possible, the robustness of new mechanisms discovered in vitro was further tested in vivo to complete a cycle.
The association of chronic low level endoplasmic reticulum (ER) stress in endothelium in regions of flow disturbance was identified in atherosusceptible sites of aorta, carotid, renal, and coronary arteries as an important adaptive biomarker of susceptible phenotype. ER stress is linked to proinflammatory and oxidative stress pathways. Examples of microRNA and transcription factor mechanisms involved in site specific endothelial phenotype heterogeneity and pro-inflammatory/susceptible status in vivo will be presented.
We propose endothelial atherosusceptibility as a systems imbalance of multiple interrelated pathways that sensitizes the cells to pathological change. However, by adjusting the balance of cellular pathways the endothelium may respond to risk factor perturbation with surprisingly protective as well as pathological outcomes, reflecting the resilient nature of endothelial adaptation to the physical and chemical environment.

TRP channels in cerebral arteries

S. Earley

Colorado State University, Fort Collins, CO, USA

The mammalian transient receptor potential (TRP) superfamily of cation channels consists of 28 members divided among six subfamilies based on sequence homology. The function of many TRP channels present in the vasculature remains unknown. A goal of my laboratory is to elucidate the physiological significance of the sole member of the ankyrin (A) TRP subfamily, TRPA1, in endothelium-dependent regulation of cerebral arteries. TRPA1 is a Ca2+-permeable non-selective cation channel activated by noxious and pungent electrophilic compounds, such as allyl isothiocyanate (AITC), a substance derived from mustard oil and allicin, a compound present in garlic. The structure of the channel is distinguished by the ~14-

19 ankyrin repeat (AR) domains present in the intracellular amino terminus. TRPA1 is thought to be involved in diverse physiological processes including nociception, mechanotransduction, and thermal and oxygen sensing. We find that TRPA1 is present in the endothelium of cerebral, but not coronary, mesenteric, renal, or skeletal muscle arteries. Furthermore, AITC-induced activation of TRPA1 causes endothelium-dependent dilation of cerebral arteries. These observations suggest that TRPA1 channels may play a critical but unknown role in the regulation of the cerebral vasculature. Physiological activators of the channel in this tissue are not known. We tested the hypothesis that lipid peroxidation products (LPP) generated by reactive oxygen species produced by NADPH oxidase (NOX) stimulate TRPA1 channels in the endothelium in an autocrine manner. We found that the LPP 4-hydroxy-nonenal (4-HNE) caused concentration-dependent cerebral artery dilation (EC50 = 8.4 μM) that was abolished by the selective TRPA1 antagonist HC-030031. Using total internal reflection fluorescent microscopy (TIRFM) to record TRPA1 Ca2+ sparklets (unitary TRPA1-mediated Ca2+ influx events), we found that the NOX substrate NADPH increased TRPA1 Ca2+ sparklet frequency in primary cerebral artery endothelial cells. This response was blocked by HC-030031. NADPH also dilated isolated and pressurized (80 mmHg) cerebral arteries with pre-developed myogenic tone in a concentration-dependent manner (EC50 = 1.2 μM). Pre-treatment with HC-030031 diminished NADPH-induced dilation, suggesting involvement of TRPA1 channel activity in this response. Significantly, 4-HNE and NADPH-induced dilation were absent from novel, endothelial cell-specific TRPA1 knockout (eTRPA1-/-) mice. Furthermore, immunolabeling studies and proximity ligation assays using primary cerebral artery endothelial cells and isolated cerebral arteries demonstrate co-localization of TRPA1, NOX2, and 4-HNE within myoendothelial junction (MEJ) sites. Together, these data indicate that NOX-derived LPP dilate cerebral arteries by activating TRPA1 in myoendothelial junctions, demonstrating a novel mechanism for the regulation of cerebral blood flow. Our findings suggest that TRPA1 channels may be a suitable target for the development of new therapies for cerebrovascular diseases associated with endothelial dysfunction, such as stroke.

Pressure-sensing by TRPC5-containing channels in aortic baroreceptor

C. Wong[1,2], B. Shen[1], O. Lau[1] and X. Yao[1]

[1]School of Biomedical Sciences, The Chinese University of Hong Kong, Hong Kong, Hong Kong and [2]Integrative Biology and Pharmacology, UT Health, Houston, TX, USA

Arterial baroreceptors contain mechanosensors that detect the change in blood pressure, and transduce the mechanical signal into electrical signal transmitted via sensory neurons. The molecular identities of the baroreceptor mechanosensor are not fully understood, however, mechanosensitive ion channels are ideal candidates due to their ability to alter membrane potential. By mechanically stimulating the aortic baroreceptor neurons isolated from rat, we recorded a cation channel current comprising TRPC5. The baroreceptor TRPC5-containing channels were directly activated by membrane stretch on the soma and the neurite terminal. The channel activity was potentiated by Gd^{3+}, but was abrogated by an anti-TRPC5 blocking antibody T5E3 and by expressing a dominant-negative TRPC5 construct T5DN. Calcium imaging and single-channel electrophysiology confirmed the mechanosensitivity of heterologously expressed mouse TRPC5 in cell lines. Disruption of TRPC5 function in rat baroreceptor neurons by lentivirus mediated delivery of T5DN cDNA impaired the high blood pressure-induced firing frequency increase of the aortic depressor nerve, and it also impaired the baroreceptor-mediated reflex control of heart rate. In TRPC5 knockout (*trpc5*$^{-/-}$) mice, the pressure-induced firing frequency increase was markedly attenuated, and the baroreflex responses were also impaired. TRPC5 thus forms a stretch-activated channel participating in the mechanotransduction at the aortic baroreceptor.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA229

Lipid-sensing TRPC channels in cardiovascular health and disease

D. Beech

University of Leeds, Leeds, UK

Transient Receptor Potential Canonical (TRPC) proteins assemble to form channels that enable influx of calcium and sodium ions. There are six TRPC proteins in humans but more than six TRPC channels may arise because of heteromers amongst TRPCs and other TRP proteins. The proteins are widely expressed and have multiple functions throughout the peripheral and central systems of the body. Modulators of the channels include lipids, redox factors, and agonists at G-protein-coupled and tyrosine kinase receptors. My research addresses fundamental understanding of how and why cells control calcium ion entry in vascular biology; particularly in adaptive processes, human disease, and therapeutics. TRPC channels are an important but not singular aspect of these calcium entry mechanisms (Beech 2013 Circ J published on-line). They are expressed throughout the vasculature and probably in all cell types of the vasculature. These channels appear to have most significance as drivers of change when there is strain or insult in physiology or disease. Intriguingly, many, but not all, of the TRPC channel modulators are lipids or lipid-soluble substances; there are 10 known lipid modulators of the TRPC5 subtype and 9 of the TRPC6 subtype. These observations suggest that TRPC channels are lipid-sensing ion channels. Some of the lipid factors act directly, others indirectly (e.g. via lipid-sensing G-protein-coupled receptors). Our recent work has identified TRPC channels in perivascular and other adipocytes, which are key cell types in the control and storage of lipids and which play primary roles in cardiovascular health. The functional significance of these channels arises through negative regulation of adiponectin, a pivotal anti-inflammatory adipokine (Sukumar et al 2012 Circ Res 111, 191-200). The work identified dietary omega-3 fatty acids as inhibitors of these adipocyte TRPC channels and revealed the striking finding that the stimulatory effect of these fatty acids on adiponectin secretion is completely abrogated by in vivo genetic disruption of TRPC ion channel function. These and other recent findings will be discussed.

SA230

TRPA1 channels and and cutaneous blood flow

A.A. Aubdool[1], R. Graepel[1], X. Kodji[1], E.S. Fernandes[1], S. Bevan[2] and S.D. Brain[1]

[1]BHF Centre of Cardiovascular Excellence and Centre of Integrative Biomedicine, King's College London, London, UK and [2]Wolfson CARD Centre, King's College London, London, UK

Cold-induced vasodilatation was first described by Lewis (1930) and remains an important phenomenon in protecting against cold-induced injury. Although this field of research has been extensively studied, the mechanisms involved in cold-induced vasodilatation currently remains unclear. The non-selective cation channel, transient receptor potential ankyrin 1 (TRPA1) is expressed in a subset of sensory neurons and was initially reported to sense noxious cold temperature. Although several studies have previously investigated its role as a cold sensor in the study of pain, its influence in cold-induced vascular responses is unknown. We have investigated the influence on peripheral vascular responses to environmental cold exposure in skin in vivo. Using non-invasive laser Doppler flowmeter techniques, peripheral blood flow was measured in anaesthetised mice before (5-10 min:baseline) and after local cold exposure of the mice hindpaw (30 min). Results were analysed as area under the response curve (AUC), expressed as mean + S.E.M. in arbitrary flux units (x1000 flux units) and analysed by 2-way ANOVA + Bonferroni's test. Cold treatment caused the expected reduction in skin blood flow, followed by a dilator response that was monitored for the following 30 min in WT mice. This response was substantially reduced in TRPA1 KO mice compared to respective age-matched WT mice (245.1 + 39.6 vs 86.1 + 11.0, x 1000 flux units, AUC, n=6, $p<0.01$) and antagonised by the TRPA1 antagonist HC030031 (100mg/kg, i.p., n=5, $p<0.001$). The cold-induced response was also shown to be significantly reduced in WT mice pre-treated with the calcitonin gene related peptide (CGRP) receptor antagonist, CGRP8-37 (400nmol/kg, i.v., n=7, $p<0.001$) and the substance P neurokinin-1 receptor antagonist SR140333 (480nmol/kg, i.v. n=5, $p<0.001$), suggesting a prominent role of neuropeptides in the cold-induced vascular responses. These results provide novel evidence of a major involvement of TRPA1 in local cold-induced vascular responses in vivo, with findings indicating a role for TRPA1-dependent neurogenic vasodilation as a key component of this response.

SA231

TRP channels as regulators of blood pressure and cardiac hypertrophy

M. Freichel

Institute of Pharmacology, Heidelberg University, Heidelberg, Germany

In the last few years, the large family of transient receptor potential (TRP) channels has been associated with the development of several cardiovascular diseases. 28 mammalian TRP-related proteins have been cloned, which are divided in 6 subfamilies: the classical TRPs (TRPC1–7); the vanilloid receptor TRPs (TRPV1–6); the melastatin TRPs (TRPM1–8); the mucolipins (TRPML1–3); the polycystins (TRPP1–3); and ankyrin transmembrane protein 1 (TRPA1). The proteins of the TRP family exhibit a 6-transmembrane domain architecture and form cation channels activated by, among others, temperature, receptor stimulation, chemical agonists, or possibly mechanical forces. In this way, they may contribute directly to transplasmalemmal Ca2+ influx and/or influence intracellular Ca2+ concentration ([Ca2+]i) indirectly by setting the membrane potential or regulating Ca2+ release from intracellular organelles. Depending on the cell type, TRP channel–mediated changes in cellular Ca2+ homeostasis can lead to alterations in vascular and cardiac contractility, neurotransmitter release, secretion of vasoactive hormones, mineral absorption, and body fluid balance to regulate blood pressure. In the heart, neuroendrocrine stimuli like noradrenaline, adrenaline and Angiotensin II lead to activation of G-protein-dependent signaling pathways that evoke Ca2+ entry and Ca2+-dependent processes, e.g. activation of Calcineurin/NFAT, CaM-Kinase and protein kinase C leading to the development of myocyte growth and cardiac hypertrophy. Although this represents an adaptive response preserving cardiac function initially, the persistent activation of this pathway during long-term cardiac stress may lead to cardiac failure in many cardiovascular disease entities including hypertension, ischemic or valvular heart disease. A specific pharmacology is still lacking for most TRPs. Therefore, studies to unravel the roles of TRP channels currently rely on experiments using transgenic animals and our findings about the role of individual TRP proteins for blood pressure regulation and development of cardiac hypertrophy using TRP-deficient mice will be presented.

Functions of the C1 neurons: a synthetic overview

P.G. Guyenet

Pharmacology, University of Virginia, Charlottesville, VA, USA

The C1 neurons reside in the rostral ventrolateral medulla (RVLM). They use glutamate as fast transmitter and synthesize catecholamines plus various neuropeptides. Only a third of the C1 neurons are presympathetic i.e. innervate sympathetic preganglionic neurons. These C1 cells include several subgroups that are organized in roughly viscerotopic manner and regulate the circulation in concert with other types of RVLM bulbospinal neurons. Other subsets of C1 cells control the parasympathetic outflow and the hypothalamic pituitary

axis including the secretion of vasopressin, oxytocin and corticotrophin releasing factor via direct projections to the dorsal motor nucleus of the vagus and the paraventricular nucleus of the hypothalamus respectively. C1 cells are variously activated by hypoglycemia, infection or inflammation, hypoxia, nociception and hypotension. Optogenetic stimulation of the C1 cells increases breathing and activates brainstem noradrenergic neurons including the locus coeruleus. Based on the various effects attributed to the C1 cells, their axonal projections and what is currently known of their synaptic inputs, we propose that subsets of C1 cells are differentially recruited by pain, hypoxia, infection/ inflammation, hemorrhage and hypoglycemia to produce a repertoire of stereotyped autonomic, metabolic and neuroendocrine responses that help the organism survive physical injury and its associated cohort of acute infection, hypoxia, hypotension and blood loss.

Respiratory modulation of sympathetic nerve activity: insights from human studies

J.P. Fisher

College of Life and Environmental Sciences, University of Birmingham, Birmingham, UK

It has been known since the earliest direct recordings that postganglionic sympathetic nerve activity shows a respiratory modulation in humans. Sympathetic outflow to the skeletal muscle vasculature reaches a nadir at peak inspiration and peaks during expiration. This pattern of activity is the net result of a complex integration of central neuronal circuits and modulatory feedback signals from cardiorespiratory sensory afferents, including lung-stretch receptors, baroreceptors, central and peripheral chemoreceptors. There is accumulating evidence from animal models and patient populations indicating that pathophysiological alterations in the respiratory modulation of sympathetic nerve activity can occur. Simms et al. (2009) reported that an altered coupling between respiration and sympathetic nerve activity is a causative factor in the elevated vascular resistance and blood pressure observed in the spontaneously hypertensive rat. We have observed an attenuation of the normal cyclical inhibition of muscle sympathetic nerve activity burst incidence during respiration in our preliminary studies of patients with essential hypertension (Fisher et al. 2011). Similar findings have been reported in patients with chronic heart failure, where a diminished sympathoinhibitory effect of the lung inflation reflex has been closely related to heightened muscle sympathetic nerve activity (Goso et al. 2001). Interestingly, acute slow deep breathing transiently reduces muscle sympathetic nerve activity in patients with hypertension (Oneda et al. 2010). Ongoing studies in our laboratory are examining the effects of a home-based training device which guides slow deep breathing (8 weeks, 15 min daily) on resting sympathetic nerve activity and its respiratory modulation in patients with hypertension.

Inhibitory regulation of sympathetic outflows

A.K. Goodchild[1], B.R. Bowman[1], P.G. Burke[1,2], S.F. Hassan[1], N.N. Kumar[1,2] and L.M. Parker[1]

[1]The Australian School of Advanced Medicine, Macquarie University, Sydney, NSW, Australia and [2]Department of Pharmacology, University of Virginia, Charlottesville, VA, USA

The destination of the sympathetic outflow which arises from sympathetic preganglionic neurons located in the thoracolumbar spinal cord is a myriad of target organs that include the vasculature, the adrenal gland, the viscera and brown adipose tissue. Much work has been directed at determining what areas of the brain influence which of these functional outflows and how this is regulated. For example, we have demonstrated that somatostatin inhibits, by way of somatostatin 2A receptors, a select population of neurons in the rostral ventrolateral medulla that regulate vasomotor tone by way of a fast conducting spinal pathway (1,2). We have combined a functional approach with anatomical analysis to investigate the neurochemicals used to control these neuronal pathways. A wide range of neurotransmitters/neuromodulators are found in presympathetic pathways that control sympathetic preganglionic neurons and in the preganglionic neurons themselves. These neurochemicals include amino acids, short lived gases and peptides. This presentation will discuss the role of inhibitory neuropeptides in the control of the sympathetic outflows named above. We have identified how specific outflows are influenced by a range of inhibitory neuropeptides in the spinal cord. The use of specific physiological stressors has permitted the identification of the neurons activated and retrograde tracing techniques allow target organ destination of neurons to be identified. Using such approaches we have defined the neurochemical codes for neurons activated by glucoprivic and hypotensive stimuli. The role of neuropeptides in particular and the colocalisation of multiple neurotransmitters in general will also be addressed.

Central respiratory-sympathetic coupling and sympathetic overactivity after chronic intermittent hypoxia

D. Zoccal

Physiology and Pathology, School of Dentistry of Araraquara, São Paulo State University, Araraquara, SP, Brazil

Chronic exposure to intermittent hypoxia (CIH) introduces significant neural plasticity in the respiratory and sympathetic networks. As a consequence, substantial changes in the mechanisms controlling respiratory and sympathetic activities can be observed in rats exposed to CIH. These include exaggerated respiratory and sympathetic chemoreflex responses, enhanced respiratory long-term facilitation and baseline sympathetic overactivity. The latter has been pointed out as an important factor contributing to the development of arterial hypertension in rats submitted to CIH. In our studies, we have been exploring the hypothesis that the enhanced sympathetic drive following CIH exposure is, at least in part, dependent on alterations in the respiratory network and its interaction with the sympathetic nervous system. We found that juvenile rats exposed to 10 days of CIH exhibited a pattern of active expiration with recruitment of abdominal muscles during late expiratory phase (late-E) in conditions of normoxia/normocapnia. Correlated with the emergence of late-E bursts in abdominal activity, we verified that sympathetic nerve of CIH rats also displayed novel bursts of activity during late-E, which were eliminated with the reduction of the central respiratory drive with hypocapnia. The abdominal and sympathetic late-E activities of CIH rats were recorded in the absence of peripheral feedback information and were associated with changes in the neuronal activity of expiratory neurons of ventral surface of medulla. Altogether, our data suggest that strengthened interactions between expiratory and sympathetic neurons contribute to elevate baseline sympathetic activity of CIH rats. These observations put forward the central respiratory-sympathetc coupling mechanisms as a novel player for the development of neurogenic hypertension.

Oxygen sensing and hypertension

J.F. Paton

Physiology & Pharmacology, University of Bristol, Bristol, UK

Many organs contain neural sensors detecting the chemical milieu. These sensors include those sensing oxygen and/or blood perfusion. They feed back afferent signals to the central nervous system triggering reflex responses that bring about appropriate homeostatic adjustment. Typically, this involves activation of the sympathetic nervous system to raise perfusion pressure in an attempt to restore adequate tissue oxygenation and blood flow within the organ from which the afferent signal originated.
Hypertension is a condition characterized by high vascular resistance, elevated sympathetic activity, T-lymphocyte vascular infiltration and inflammation, and vascular hypertrophy. These symptoms all hamper organ blood flow and oxygenation. Our working hypothesis is that the organs that are most sensitive to restriction in blood flow and reduced oxygenation (i.e. hypoperfusion) are likely to be critical for life and contribute greatest to reflexly evoked increases in sympathetic activity and hypertension. These organs are the brain and carotid body chemoreceptors. After all, carotid body function in ensuring adequate oxygenation of the brain may be the most important one they possess.
The relative contribution of brainstem hypoperfusion, carotid body activation and the interaction between these organs in hypertension will be discussed. My presentation will include reciprocating translational studies between animal models with hypertension and hypertensive patients. I will present data revealing elevated cerebral vascular resistance in hypertension that occurs prior to the onset of the hypertension. I will report on a novel intra-cranial detector system that when activated by cerebral hypoperfusion produces sustained hypertension. As a putative transduction mechanism for the detection of cerebral hypoperfusion, and resultant sympathoexcitation, I will discuss the role of TRPV4 channels. An issue with cerebral perfusion in hypertension may be due to a paucity of parasympathetic vasodilator fibre innervation and poor functional hyperaemic responses: I shall provide evidence describing such changes. I will also show that carotid body chemoreceptors not only have heightened reflex sensitivity but also tonicity in hypertension. Although it is well known that repeated stimulation of the carotid body triggers hypertension and increases in sympathetic nerve activity, we have found that this is, in part, mediated via an adrenomedullin mediated mechanism in the rostral ventrolateral medulla and enhanced central respiratory-sympathetic coupling. Our recent results show that hypertension and excessive sympathetic nerve activity can be alleviated by removing carotid body afferent feedback, which reduces the excitatory synaptic coupling of respiratory cells innervating pre-sympathetic motoneurones. Based on these results, I will discuss novel therapeutic interventional approaches to treat drug-resistant hypertension in humans.

Neuronal voltage-gated calcium channels: the role of auxiliary $\alpha 2\delta$ subunits in channel trafficking and in neuropathic pain

A.C. Dolphin

Neuroscience Physiology and Pharmacology, University College London, London, UK

The $\alpha 2\delta$ auxiliary subunits of voltage-gated calcium channels enhance calcium currents and affect their properties, but their mechanism of action is not well understood. We have recently shown that $\alpha 2\delta$ subunits are glycosyl phophatidyl inositol (GPI)-achored proteins (Davies et al., 2010), and this is essential for their function, and explains their localization in lipid raft fractions (Davies et al., 2006). The anti-epileptic and anti-nociceptive drugs gabapentin (GBP) and pregabalin (PGB) are known to bind to $\alpha 2\delta$-1 and $\alpha 2\delta$-2, and the $\alpha 2\delta$-1 target is essential for the antihyperalgesic action of this drug (Field et al., 2006). We have found that acute application of GBP does

not affect calcium currents in several different systems. However, chronic application of GBP to cultured cells reduces both calcium currents and cell-surface expression of heterologously expressed α2δ and α1 subunits (Hendrich et al., 2008), and PGB also affects α2δ trafficking in vivo (Bauer et al., 2009). This process involves an inhibition of trafficking through the recycling endosomes (Tran-Van-Minh & Dolphin, 2010). Our evidence indicates that gabapentinoid drugs act chronically to impair the trafficking function of α2δ subunits and the associated α1 calcium channel subunits.

Evidence from numerous studies has identified an important role for α2δ-1 in neuropathic pain. The mRNA and protein for α2δ-1 are up-regulated in dorsal root ganglion (DRG) neurons following spinal nerve ligation (SNL), a model of neuropathic pain, an increase which correlates with the onset of mechanical hypersensitivity (Bauer et al., 2009). In a recent study, we have examined the role of α2δ-1 in sensory neuron function by examining sensory processing and the development of experimental neuropathic pain in α2δ-1 knockout mice (Fuller-Bicer et al., 2009). We have found that α2δ-1 gene deletion results in reduced baseline sensitivity to cold and mechanical stimuli, and a marked delay in the onset of mechanical hypersensitivity following nerve injury. This is coupled with a reduction in the proportion of DRG neurons sensitive to menthol in α2δ-1 knockout mice, suggesting defects in specific sensory modalities and that α2δ-1 is essential for the rapid development of behavioural hypersensitivity following nerve damage

Neuronal dysfunction in genetic prion diseases: mutant prion protein impairs delivery of voltage-gated calcium channels to the presynaptic membrane

R. Chiesa

Neuroscience, Mario Negri Institute for Pharmacological Research, Milan, Italy and Dulbecco Telethon Institute, Milan, Italy

How mutant prion protein (PrP) leads to neurological dysfunction in genetic prion diseases is unknown. Tg(PG14) mice synthesize a misfolded mutant PrP which is partially retained in the neuronal endoplasmic reticulum (ER). As these mice age, they develop ataxia and massive degeneration of cerebellar granule neurons. We report that motor behavioral deficits in Tg(PG14) mice emerge before neurodegeneration and are associated with defective glutamate exocytosis from granule neurons due to impaired calcium dynamics. We found that PrP interacts with the voltage-gated calcium channel α2δ-1 subunit which promotes the anterograde trafficking of the channel. Owing to ER retention of mutant PrP, α2δ-1 accumulates intracellularly, impairing delivery of the channel complex to the cell surface. Thus mutant PrP disrupts cerebellar glutamatergic neurotransmission by reducing the number of functional channels in cerebellar granule neurons. These results link intracellular PrP retention to synaptic dysfunction, indicating new modalities of neurotoxicity and potential therapeutic strategies.

CRMPs curb calcium channels for cessation of chronic pain: an old target engages a new partner

R. Khanna

Pharmacology and Toxicology and Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN, USA and Program in Medical Neurosciences, Paul and Carole Stark Neurosciences Research Institute, Indiana University School of Medicine, Indianapolis, IN, USA

The use of N-type voltage-gated calcium channel (CaV2.2) blockers in pain therapeutics is limited by numerous physiologic side-effects. Here we report suppression of inflammatory and neuropathic hypersensitivity by inhibiting binding of collapsin response mediator protein 2 (CRMP-2) to CaV2.2, thus reducing channel function. A peptide of CRMP-2 fused to the HIV TAT protein (TAT-CBD3) decreases neuropeptide release from sensory neurons and excitatory synaptic transmission in dorsal horn neurons, reduces meningeal blood flow, reduces nocifensive behavior induced by formalin injection or corneal capsaicin application, and reverses neuropathic hypersensitivity produced by an antiretroviral drug. TAT-CBD3 was mildly anxiolytic without affecting memory retrieval, sensorimotor function, or depression. At doses 10-fold higher than that required to reduce hypersensitivity in vivo, a transient episode of tail kinking and body contortion was observed. By preventing CRMP-2-mediated enhancement of CaV2.2 function, TAT-CBD3 alleviates inflammatory and neuropathic hypersensitivity, an approach that may prove useful in managing chronic pain. Remarkably, sympathetic-associated cardiovascular activity is not affected by TAT-CBD3. Peptide analgesics, such as TAT-CBD3 and its derivatives, with restricted access to the CNS represent a completely novel approach to the treatment of severe pain with an improved safety profile.

[1]Dept. of Biophysics, Saarland University, Homburg, Germany, [2]Tuebingen Hearing Research Centre, University of Tuebingen, Tuebingen, Germany, [3]Institute of Neurobiology, University of Ulm, Ulm, Germany, [4]Institute of Neurobiology, University of Tuebingen, Tuebingen, Germany, [5]Institute of Neurobiology II, University of Leipzig, Leipzig, Germany, [6]Center for Molecular Neurobiology, University of Hamburg, Hamburg, Germany, [7]Dept. of Biology, University of Kaiserslautern, Kaiserslautern, Germany, [8]Dept. of Otolaryngology, Saarland University, Homburg, Germany and [9]Dept. of Physiology and Medical Physics, Innsbruck Medical University, Innsbruck, Austria

The ascending auditory pathway consists of the auditory periphery, including mechanosensitive hair cells in the cochlea, spiral ganglion neurons forming the auditory nerve, and at least five stations until sound reaches the auditory cortex. All synapses along this pathway require proper expression and function of presynaptic Ca^{2+} channels for triggering transmitter release. Voltage-gated calcium channels (VGCCs) are protein complexes composed of an α_1 pore-forming subunit and auxiliary subunits β and $\alpha_2\delta$. VGCCs of cochlear inner hair cells (IHCs) are mainly composed of the α_1 subunit $Ca_v1.3$ (contributing to ~90% of I_{Ca}; refs. 1,2) and $\beta2$ (contributing to ~70% of I_{Ca}; ref. 3), and lack of $Ca_v1.3$ or $\beta2$ causes deafness.

Auxiliary subunits assist in trafficking and membrane surface expression of VGCCs and modulate their biophysical properties. Recently, novel roles for $\alpha_2\delta$ in synapse development have been suggested (refs. 4,5). So far, expression and contribution of the four $\alpha_2\delta$ subunits $\alpha_2\delta1$-4, and their specificity for the pore-forming α_1 and auxiliary β subunits are still unknown.

Because quantitative PCR revealed the expression of $\alpha_2\delta2$ in IHCs at pre-hearing and hearing age, we here analyzed hearing and IHCs of ducky mice ($\alpha_2\delta^{du/du}$), a mouse line with a mutation in the *cacna2d2* gene encoding a non-functional $\alpha_2\delta$ protein. Auditory brainstem response (ABR) click thresholds were increased by 18.3 dB in the mutants, and frequency ABR showed a significant elevation of hearing thresholds by about 20 dB between 11.3 and 22.6 kHz ($n \geq 11$ ears). Distortion-product otoacoustic emission (DPOAE) amplitudes were slightly larger in $\alpha_2\delta^{du/du}$ compared with wild-type animals, indicating normal outer hair cell (OHC) function. Synaptic morphology, as assessed by immunolabelling, revealed normal expression of presynaptic $Ca_v1.3$ and $\beta2$ as well as postsynaptic GluR2/3-proteins in close apposition with synaptic ribbons in IHCs of $\alpha_2\delta^{du/du}$ mice. However, both peak Ca^{2+} and peak Ba^{2+} current densities of $\alpha_2\delta^{du/du}$ IHCs were reduced by 29 % ($n \geq 11$). Moreover, the voltages for half-maximum activation of Ca^{2+} and Ba^{2+} currents were shifted to more positive potentials by 5 mV and 7 mV, respectively, whereas the voltage sensitivities (steepness of the activation curves) were unaffected. Inactivation of Ca^{2+} and Ba^{2+} currents over 300 ms depolarization steps was unchanged.

These results are in accordance with the classical role of $\alpha_2\delta$ subunits in surface expression and gating modulation of VGCCs. In wild-type IHCs, $Ca_v1.3$ and $\beta2$ appear to co-assemble with $\alpha_2\delta2$. Lack of $\alpha_2\delta2$ cannot be fully compensated, because of reduced IHC Ca^{2+} currents causing a moderate hearing impairment.

We detected another form of hearing impairment in a mouse line carrying a targeted deletion of $\alpha_2\delta3$ ($\alpha_2\delta3^{-/-}$; ref. 6). ABR hearing thresholds were slightly but significantly higher in $\alpha_2\delta3^{-/-}$ mice by 5 dB and 8-19 dB for click and pure tone stimuli, respectively, compared with wild-type littermates. Additionally, ABR waveforms showed a reduction in the amplitude of wave II and distortion of waves III and IV in $\alpha_2\delta3^{-/-}$, suggesting impaired signal transmission along the auditory pathway. In behavioral experiments, $\alpha_2\delta3^{-/-}$ mice learned to discriminate pure tones but completely failed to discriminate temporally structured amplitude-modulated tones, as demonstrated by an aversive go/no-go shuttle-box paradigm. IHCs of $\alpha_2\delta3^{-/-}$ mice had robust Ba^{2+} currents through Ca^{2+} channels and normal numbers of $Ca_v1.3$-immunopositive spots, which were co-localized with synaptic ribbons. Together with normal DPOAE amplitudes in $\alpha_2\delta3^{-/-}$ mice, these data suggest that deletion of $\alpha_2\delta3$ does not impair IHC and OHC function. $\alpha_2\delta3$ expression was predominant in spiral ganglion neurons and in auditory brainstem nuclei. Impaired synaptic transmission from auditory nerve fibers to bushy cells was confirmed by juxtacellular in-vivo recordings of sound-evoked activity, which revealed shallower rate-level functions and increased latencies at these synapses in $\alpha_2\delta3^{-/-}$ mice. Sizes of auditory nerve fiber synaptic boutons, which terminate at the somata of bushy cells, were significantly smaller in mutants, and the level of $Ca_v2.1$ channel immunoreactivity was reduced. These results identify a novel role for the $\alpha_2\delta3$ auxiliary subunit in establishing and maintaining the morphology and function of specific synapses

in the mammalian auditory pathway and identify the $\alpha_2\delta 3$ gene as a potential candidate gene for an auditory processing disorder.

Pharmacological relevance of intestinal drug transporters

I. Tamai

Kanazawa University, Kanazawa, Ishikawa, Japan

Although there are many suggestions for the contribution of efflux transporters in intestinal secretion/barrier of drugs mediated by ABC transporter, information on the absorptive/influx transporter molecules responsible for the intestinal absorptive process is limited. Organic anion transporting polypeptides (OATP; SLCO) family is expressed in various tissues including intestine and liver (1). OATP1B1 and OATP1B3 are selectively expressed in liver basolateral membrane thereby contributing in hepatic uptake of xeno- and endo-biotics such as bile acids and conjugated metabolites of bilirubin and steroids hormones. Those OATPs accept clinically used drugs such as statins and others. Effect of genetic polymorphism of OATP1B1, which cause altered activity, on pharmacokinetics of its substrate drugs clarified in vivo significance of OATP1B1(1). Accordingly, based on such a pharmacological relevance, OATPs are well recognized as physiologically and pharmacologically important transporters. OATP molecules are expressed in intestine and we tried to clarify its role in intestinal absorption of drugs. OATP2B1 (OATP-B, SLCO2B1) is expressed at the apical membrane of human intestinal epithelial cells and accepts similar compounds with hepatic OATPs as substrates (2,3). Accordingly, it is possible that OATP2B1 may drug absorption due to its broad substrate selectivity, while it is not easy to demonstrate its in vivo relevance to intestinal absorption. We found that genetic variant SLCO2B1*3, which has mutation c.1457>T that causes the amino acid change S486F, showed a decreased transport activity of estrone-3-sulfate (E3S), which is a physiological substrate of OATP2B1 (3). Fexofenadine (FEX), an anti-allergic agent is a substrate of OATP2B1, and OATP2B1 was thought to be the mechanism of its intestinal absorption, while there was no evidence of in vivo contribution of OATP2B1. Accordingly, we tested effect of genotype, SLCO2B1*3 (c.1457>T), on intestinal absorption of FEX after oral administration (3). As the results AUCs in individuals with genotype TT showed lowest plasma exposure of FEX, demonstrating in vivo contribution of OATP2B1 in the drug absorption. Another evidence of in vivo relevance of OATP2B1 was obtained by interaction of FEX absorption with fruit juices (FJ). When taking drugs orally with grapefruit juice (GFJ) and apple juice (AJ), plasma concentrations of substrate drugs of OATP2B1, including FEX and beta-adrenergic receptor antagonist talinolol, are affected (3). When examined inhibitory effect of those FJ on OATP2B1 by in vitro OATP2B1-expressing cultured cells, all FJs decreased apparent uptake of E3S via OATP2B1 at diluted concentration lower than 10% (4). These in vitro FJ effects strongly suggest that OATP2B1 is responsible for drug absorption. Further studies suggested that the responsible components in GFJ as inhibitors include naringin, hesperidin and others, while it was not clear in AJ. However, by uptake studies using in vitro OATP2B1-expressed cells, naringin showed differential inhibitory effect depending on used substrates, demonstrating substrate selective inhibitory effect. In addition, concentration dependence in E3S uptake by OATP2B1 showed biphasic kinetics. Therefore, it is possible that there are multiple binding sites (MBS) on OATP2B1 which show different substrate and inhibitor selectivity (5). MBS may cause dose/concentration dependence by mainly contributing binding sites on OATP2B1. Accordingly, MBS hypothesis may explain apparently discrepant in vitro and in vivo observations as well as broad substrate selectivity of OATP2B1. More interestingly, AJ but not GFJ decreased OATP2B1 activity even by only preincubation without co-existence during uptake measurement, namely long-lasting effect (6). Although the mechanism of long-lasting effect of AJ is not clear, it is known that OATP2B1 protein is internalized by protein-kinase C activation, thereby showing reduction of apparent uptake activity (7). When we exposed OATP2B1-expressing cultured cells with AJ and analyzed protein localization using antibody, intracellular localization was apparently changed by exposing with AJ. Accordingly, AJ effect might be explained by altered intracellular localization of OATP2B1 protein.

In conclusion, OATP2B1 should be responsible for absorption of various compounds including clinically used drugs. MBS may contribute to a broad substrate specificity of OATP2B1. In addition, clinical observation in OATP2B1-mediated absorption and interaction may be complex due to MBS and change in trafficking of OATP2B1 proteins by any co-administered drugs or food/juice. Most of information on OATP2B1, especially in vivo observation, came from the studies using drugs. According utilization of clinically used drugs as probes to monitor transporter activity is useful.

Polyspecific transporters as powerful pharmacological targets: the case of PEPTs (*SLC15*) and OCTs (*SLC22*)

M. Sala-Rabanal

Department of Cell Biology & Physiololgy, and CIMED, Washington University, St. Louis, MO, USA

The proton-dependent oligopeptide transporters (PEPTs, *SLC15*) and the organic cation transporters (OCTs, *SLC22*), two

mechanistically very distinct families within the Major Facilitator Superfamily (*Transporter Classification Database*, www.tcdb.org), share a common thread: a broad substrate selectivity, which in recent years has been subject to intense scrutiny, driven by the prospect of using these carriers for the delivery of drugs and prodrugs. Their relatively tolerant recognition and binding requirements, together with their localization to barrier epithelia and organs of drug disposition, make the PEPTs and the OCTs prime candidates for rational drug design, but these same properties can lead to competitive drug-drug interactions or toxicity in non-target organs. Pharmacological, structural and computational studies contribute to the refinement of existing pharmacophore models, towards improved targeting strategies and the prevention of undesired side effects.

PEPT1 (*SLC15*A1) and PEPT2 (*SLC15*A2) are mainly expressed, respectively, in the brush-border membrane of enterocytes, and in the apical membrane of renal proximal tubular cells, the lung epithelium and the choroid plexus, where they mediate the absorption, reabsorption and accumulation of all di- and tripeptides resulting from the hydrolysis of dietary and endogenous protein. In addition, they have been shown to recognize a broad spectrum of pharmacologically active compounds, both peptidomimetic, such as the β-lactam antibiotics, and non-peptidic. By means of biochemical and electrophysiological assays in *Xenopus* oocytes, we showed that the widely-prescribed antibiotics ampicillin, amoxicillin, cephalexin, cefadroxil, and the antineoplastics bestatin and δ-aminolevulinic acid are transported by human PEPT1 and PEPT2, and we established the alternating-access mechanism by which both oligopeptides and xenobiotics are translocated (Sala-Rabanal, Loo et al. 2006, Sala-Rabanal, Loo et al. 2008). The drugs, however, were transported with much lower efficiency than the natural substrates, and our findings suggest that the presence of physiological concentrations of dietary peptides in the gut may reduce or delay the absorption of oral delivery drugs, which should thus be taken in an empty stomach.

In humans, OCT1 (*SLC22*A1) and OCT2 (*SLC22*A2) are predominantly expressed in hepatocytes and proximal tubular cells, whereas OCT3 (*SLC22*A3) is found in placenta, bronchial and intestinal epithelium, and astrocytes. OCTs interact with many natural and xenobiotic monovalent cations and have been reported to transport dicationic compounds, including the short polyamine putrescine. In a recent study, we used *Xenopus* oocytes expressing mammalian OCT1, OCT2, or OCT3 to demonstrate that spermidine, which is longer and carries an additional positive charge, is also transported by the OCTs; and that, as for monovalent cations, hydrophobicity is a major requirement for recognition in polyvalent OCT substrates and inhibitors (Sala-Rabanal, Li et al. 2013). The identification of OCTs as relevant polyamine exchange systems may contribute to further our understanding of the physiological roles of polyamines, and aid in the design of polyamine-like OCT-targeted drugs: carcinogenesis and tumor growth have been associated with increased intracellular polyamine levels, and thus the OCTs might be targeted for the delivery of cytotoxic polyamine analogs or polyamine-conjugated imaging probes.

The role of folate transporters in folate homeostasis and the targeted delivery of pharmacological agents to cancer cells

I. Goldman

Medicine and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, USA

The folates (vitamin B9) are a family of one-carbon donors required for biosynthetic processes in mammalian cells. Their absorption in the gut, transport to systemic tissues and across epithelia is mediated by three specific processes: (i) The proton-coupled folate transporter (PCFT-SLC46A1) mediates folate absorption across the apical brush-border membrane of the proximal small intestine and across the blood:choroid plexus:cerebrospinal fluid barrier. This process is electrogenic and optimal at pH ~5.5. As the pH increases the influx Kt increases and the Vmax decreases. (ii) The reduced folate carrier (RFC-SLC19A1) is ubiquitously expressed and is the major route of transport of folates into systemic tissues. RFC functions optimally at pH 7.4 and is an organic phosphate antiporter that produces large electrochemical-potential differences for folates across cell membranes. (iii) Folate receptors (FRα & FRβ) are GPI-anchored membrane glycoproteins that transport folates by an endocytic process. FRα is expressed at the apical (luminal) membrane of the renal proximal tubules, retinal pigment epithelial cells and the choroid plexus. FRβ is expressed in cells of hematopoietic origin. All the transporters are expressed in placenta; however, the absence of any one of these transporters, 00alone, does not impair placental function. There are gene-targeted mouse models for these transporters. RFC -/- is embryonic lethal; however, if the dams are folate-supplemented, the pups are normal at birth but die within two weeks due to atrophy of the hematopoietic organs. The FRβ -/- mouse has no phenotype. The FRα -/- mouse is embryonic lethal but when the dams are folate-supplemented pups are normal and their requirement for supplementation does not persist. Adult animals are fertile with a normal phenotype save for a slight folate deficiency. PCFT -/- mice are normal at birth but subsequently develop severe folate deficiency and neurological defects. The human counterparts include: (i) hereditary folate malabsorption, due to loss-of-function mutations in the PCFT gene, is characterized by signs and symptoms of severe systemic and neural folate deficiency, (ii) cerebral folate deficiency due to mutations in FRα resulting in neurological defects that, unlike in FRα -/- mice, manifest several years after birth.

All three transporters are expressed in human cancers and have a role in cancer therapeutics. The classical antifolate, methotrexate - a dihydrofolate reductase inhibitor that causes tetrahydrofolate depletion, is transported via RFC with an influx Kt of ~ 5 μM. Resistance to this drug has been associated with loss-of-function mutations in, or loss of expression of, RFC. Recently, a second-generation much more potent antifolate of this class, pralatrexate, was approved for cancer treatment, with an influx Kt of 0.05 μM. Pemetrexed is another recently

approved antifolate which, in its active (polyglutamate) forms synthesized in cells, is a direct inhibitor of one-carbon utilization in thymidylate and purine synthesis. While this agent has an affinity for RFC somewhat greater than MTX, its PCFT-mediated transport is better preserved than most other folates at neutral pH so that the drug's antitumor activity is sustained even in the absence of RFC.

A major emphasis of contemporary drug development in cancer therapeutics is on (i) identifying intracellular targets that drive proliferation of malignant cells and (ii) the development of "targeted" agents that selectively block these processes. Another approach involves the development of agents that utilize specific transporters that are primarily expressed and/or are functional in cancer, but not normal, cells. Since RFC is the major route of transport into normal tissues, it plays a major role in antifolate toxicity. On the other hand, while PCFT is ubiquitously expressed, it does not play an important role in the delivery of folates or antifolates into normal tissues at physiological pH. Drugs are being developed that have a very low affinity for RFC but a very high affinity for PCFT which operates more efficiency in the acid microenviroment of solid tumors. Folate receptors are highly expressed in a variety of epithelial tumors (FRα) and hematological malignancies (FRβ). In a different approach antineoplastics, structurally unrelated to folates, are coupled to folic acid through linkers that include a cleavable sulfhydryl bond. The complex is endocytosed and, when the reducing potential of the endosome is increased, the bond is broken and the drug, which must be lipid soluble, diffuses out of the endosome to reach its intracellular target. A similar strategy is being used to ablate macrophages, which express FRβ, for the treatment of inflammatory diseases.

Regulated trafficking of concentrative nucleoside transporters (CNTs) to the plasma membrane: a key event in nucleoside-derived drugs action

P. Fernández-Calotti[1,2] and M. Pastor-Anglada[1,2]

[1]Department of Biochemistry and Molecular Biology. Institute of Biomedicine (IBUB), University of Barcelona, Barcelona, Spain and [2]Centro de Investigación Biomédica en Red-Enfermedades Hepáticas y Digestivas (CIBER EHD), Barcelona, Spain

Nucleoside analogues (NA) constitute an important class of pro-apoptotic antimetabolites used in the treatment of hematological malignancies, solid tumors, and infectious diseases such as AIDS and hepatitis (1, 2). These therapeutic compounds include various pyrimidine and purine analogues (1) that mimic physiological nucleosides in terms of uptake into the cell and metabolism. Nucleosides and nucleoside derived drugs are hydrophilic molecules and diffuse slowly across cell membranes, thus, specific membrane proteins mediate their translocation from the extracellular milieu into the cytoplasm and, in some cases, from the cytoplasm towards the extracellular milieu. This cellular uptake occurs via nucleoside-specific membrane transporters (NT), belonging to the solute carrier families SLC28 and SLC29, encoding the concentrative (hCNT), which are Na+-dependent, and equilibrative (hENT), which are Na+-independent transporters, respectively. NA entrance into cells contribute to drug bioavailability and hence to cytotoxicity or antiviral capacity of nucleoside-derived drugs.

Among NT, hCNT proteins mediate concentrative high-affinity nucleoside influx by coupling substrate translocation to the inwardly directed electrochemical sodium gradient. This family comprises three members: hCNT1, hCNT2, and hCNT3. hENT proteins mediate facilitated, sodium-independent nucleoside-derived drug translocation. hENT1 and hENT2 are major determinants of equilibrative drug transport across the plasma membrane.

Resistance to NA treatments is usual in clinics. A key event in resistance is drug availability and entrance into the cells through NT. This is why the expression and activity of those molecules at the plasma membrane are essential.

Regulation of nucleoside transport activity in an isoform-specific manner is a suitable approach to modulate nucleoside-derived drug bioavailability. In this sense, it was shown that hCNT3 protein is retained intracellularly in a subpopulation of chronic lymphocytic leukemia (CLL) cases, showing that those patients with elevated levels of intracellular hCNT3 achieved a lower complete response rate after the purine analog fludarabine therapy (3). We have recently reported that all-trans retinoic acid (ATRA) induces hCNT3 trafficking to the plasma membrane, causing an increase in hCNT3 transporter activity and consequently fludarabine entrance in all fludarabine-resistant CLL samples analyzed (4). This effect was partially mediated by TGF-β1 by a mechanism that was dependent on the activation of the mitogen-activated protein (MAP) kinases p38 and ERK1/2 (5). Moreover, a reversion of fludarabine insensitivity was achieved in fludarabine-resistant CLL samples after ATRA or TGF-β1 treatment.

We have also found that induced traffic of NT to the plasma membrane seems to be involved in the combination therapy involving interferon α (IFNα) and the broad spectrum antiviral ribavirin, a purine nucleoside derivative drug. IFNα was shown to significantly increase the effect of ribavirin over the viral load (6). Although in basal conditions hENT1 is the main ribavirin transporter (7), no studies have evaluated the role

of hCNT2, a putative ribavirin good transporter, in the presence of IFNα. We recently demonstrated that IFNα induces a transient increase in hCNT2 activity within 15 minutes in HHL5-hepatocytes cells. This increase seems to be dependent on the translocation of hCNT2 containing vesicles to the plasma membrane by an ERK1/2 activation and microtubule integrity (Pinilla-Macua, Fernández-Calotti and Pastor-Anglada, submitted).

It is clear that NT expression is variable and that the available evidence supports a putative role for NT in nucleoside-derived drug bioavailability and responsiveness. NT expression pattern analysis might be useful as a biomarker of drug metabolism and action or as a predictor of response to therapy and patient outcome. Thus, major efforts should be made to determine the biological basis for the specific regulatory properties of NT trafficking as a way to improve cancer and viral therapies.

Physiological and pharmacological insights from OATP uptake transporter knockout mice

A.H. Schinkel

Molecular Oncology, The Netherlands Cancer Institute, Amsterdam, Netherlands

Organic anion transporting polypeptides (OATPs, gene name SLCO) are uptake transporters for a broad range of endogenous compounds and xenobiotics. To investigate the physiological and pharmacological roles of Oatp1a/1b transporters, we generated and analyzed mice lacking all Slco1a/1b genes, and humanized transgenic rescue mice overexpressing human OATP1B1 and OATP1B3 in the liver. Slco1a/1b$^{-/-}$ mice were viable and fertile but suffered from marked conjugated hyperbilirubinemia, likely due to impaired hepatic (re-)uptake of bilirubin-glucuronide (Van de Steeg et al, 2010). These mice also displayed increased plasma levels of unconjugated bile acids. Using Oatp1a/1b and Abcc3 knockout mice and the OATP1B1 and OATP1B3 transgenic mice, we could show that in normal liver Oatp1a/1b, OATP1B1, OATP1B3, and the multispecific sinusoidal export pump Abcc3 drive a detoxification-enhancing liver-blood shuttling loop for bilirubin glucuronide. Within liver lobules, this shuttle allows flexible transfer of bilirubin- and probably also drug-conjugates formed in upstream hepatocytes to downstream hepatocytes. This likely helps to prevent saturation of further detoxification processes (e.g., biliary excretion) and subsequent hepatocyte toxic injury in the upstream hepatocytes. In close collaboration with Dr. M. Jirsa (Charles University, Prague), we subsequently demonstrated that the human Rotor syndrome, a benign hereditary conjugated hyperbilirubinemia, is a two-gene disorder, caused by impaired hepatocellular (re-)uptake of bilirubin glucuronide and other compounds owing to complete deficiencies of OATP1B1 and OATP1B3 (Van de Steeg et al, 2012). Since even partial OATP1B1 deficiencies cause life-threatening drug hypersensitivities in humans, the newly identified OATP1B1 and OATP1B3 null mutations likely confer substantial drug toxicity risks. Slco1a/1b$^{-/-}$ mice not only showed decreased hepatic uptake and increased systemic exposure of the anionic drug methotrexate, but also of the bulky hydrophobic anticancer drug paclitaxel. Humanized OATP1B1 and OATP1B3 could mostly rescue these phenotypes, suggesting a similar functional importance of these proteins in humans (Van de Steeg et al, 2013). Some Oatp1a/1b proteins are also expressed in the small intestine and thought to contribute to the intestinal uptake of orally administered drugs. However, despite extensive efforts, we have so far been unable to demonstrate any effect of the Oatp1a/1b knockout on the intestinal uptake of methotrexate, fexofenadine, or pravastatin (Van de Steeg et al, 2010; Iusuf et al, 2013). In conclusion, variation in OATP1A/1B activity due to genetic variation and pharmacological inhibition, or differences in tumor-specific expression levels might affect plasma, tissue, and tumor levels of these drugs in patients, and hence their therapeutic efficacy. The developed mouse models will provide excellent tools to study such questions.

Development of the cardiac conduction system

V. Christoffels

Anatomy, Embryology and Physiology, Academic Medical Center, Amsterdam, Netherlands

The contraction pattern of the cardiac chambers is controlled by myocytes of the pacemaker and the conduction system. In the developing heart all cardiac myocytes initially possess pacemaker properties. However, the majority of the embryonic myocytes differentiates into working myocardium, and only a small population of these cells will form the sinus node and the atrioventricular (AV) node and bundle. The development of these nodal regions is achieved by highly localized suppression of working muscle differentiation and stimulation of the pacemaker gene programs. Key transcription factors that

control this process have been identified, including T-box transcription factors Tbx3 and Tbx5.
During development, the AV canal myocardium is responsible for the AV conduction delay. This type of myocardium is highly evolutionary conserved in vertebrates and will form the AV node in higher vertebrates like birds and mammals. Recently, we identified a distinctive sinus node cell population in the fish heart, revealing deep conservation of these cells as well.
Despite the electrophysiological similarities between myocytes of the sinus node and the AV node and conduction system, their molecular programs show striking differences. For example, Tbx18, Shox2 and Isl1 uniquely control sinus node development, whereas Tbx2 and Nkx2-5 control AV canal formation.
In this presentation, I will show experimental findings on the molecular mechanisms of differentiation and morphogenesis of the pacemaker tissues of the heart, and discuss how misregulation of AV canal development can lead to formation of accessory pathways and ventricular preexitation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Optical mapping of the sinus and atrioventricular nodes

V.V. Fedorov

Physiology and Cell Biology, The Ohio State University, Dublin, OH, USA

Since Keith and Flack's anatomical discovery of the Sino-Atrial Node (SAN), the primary pacemaker of the human heart, the question of how such a small SAN structure can pace the entire heart has remained for a large part unanswered. There is a paucity of information regarding physiological function of the SAN in normal and diseased human heart at the cellular, tissue, and organ levels. Recent advances in optical mapping technology have made it possible to unambiguously resolve the origin of excitation and conduction within the animal and human atrial pacemaker complexes including SAN. The combination of high-resolution optical mapping and histological structural analysis reveal that the human SAN and atrioventricular (AVN) are functionally insulated from the surrounding atrial myocardium, except for several critical conduction pathways. Indeed, the atrial pacemaker clusters including SAN and AVN require anatomical (fibrosis, fat, and blood vessels) and/or functional barriers (paucity of connexins), in order to protect them from the hyperpolarizing influence of the surrounding atrium. The presence of conduction barriers and pathways may help explain how a small cluster of pacemaker cells in the atrial pacemaker complex manages to depolarize different, widely-distributed areas of the right atria as evidenced functionally by exit points and breakthroughs. The autonomic nervous system and humoral factors can further regulate conduction through these pathways, affecting pacemaker automaticity and ultimately heart rate. Moreover, the conduction barriers and multiple pathways can form substrates for reentrant activity and thus lead to atrial flutter and fibrillation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA249

HCN channelopathies and sinus node arrhythmias

D. DiFrancesco

Dept Biosciences, University of Milano, Milano, Italy

It is generally agreed that the major role played by the funny current in the heart relates to the generation of normal, physiological pacemaker activity in the cardiac pacemaker region, the sinoatrial node (SAN), and to the control of heart chronotropism, although the exact degree by which funny channels contribute to govern pacemaking within the framework of the more complex set of partecipating mechanisms is still strongly debated. Several experimental and theoretical results provide evidence for the role of If in pacemaking. Among these results, of practical impact are applications of the concept of funny channel-based pacemaking of clinical relevance; starting from molecular/cellular properties, these applications translate the concept to the more integrated level of cardiac health in a clinical setting.
In a first example, the correlation between expression of funny channels, or more specifically of their molecular correlates HCN channels, and spontaneous activity is the basis for proof-of-concept development of "biological pacemakers". In cell-based models, it has been shown that spontaneously beating ESC-derived myocytes, known to express If, can pace cultures of neonatal rat cardiac myocytes and generate ectopic rhythms when injected in the ventricle of animal models after ablation of the AV node (Rosen et al., 2011). The aim of these protocols is to develop potential alternatives to electronic pacemakers.
In a second example, a most important clinical exploitation of funny channel properties relates to the pharmacological control of heart rate. Many funny channel-targeted drugs have been developed so far, among which ivabradine, the only drug marketed today for use in chronic stable angina and heart failure. Ivabradine is a specific blocker of funny channels, a property leading to a therapeutically useful "pure" heart rate slowing action (DiFrancesco & Camm, 2004). Ivabradine-induced block of funny channels has been analyzed in detail and shown to be characterized by a marked "use dependence", which may favour increased drug efficiency, as a rate-reducing agent, at high heart rates (tachycardia).
In a third example, several studies have shown recently that mutations in HCN4, the HCN isoform most highly expressed in pacemaker tissue, are associated with inheritable forms of arrhythmias and have provided growing evidence for a role of dysfunctional funny channels in rhythm disorders. Reported HCN4 mutations are associated with asymptomatic and symptomatic sinus bradycardia, tachycardia-bradycardia syndrome, AV node block, atrial fibrillation and contribute to more complex arrhythmias (Baruscotti et al., 2010).
The above studies, together with evidence from studies of HCN knockout mice (Bucchi et al., 2012) and data from the clinical use of ivabradine (Cappato et al., 2012), indicate that the role of funny channels need not be confined to control of physiological pacemaker activity of the SAN, but can also be relevant to maintenance of normal rhythmic activity in a broader context.
If has a recognized pathophysiological role in heart failure, since transcription of HCN channels increases in hypertrophied ventricles of failing hearts and predisposes to enhanced ventricular automaticity. Also, reduction of funny channel expression in pacemaker cells of cardiac-specific, inducible HCN4 KO mice eventually leads to lethal AV block, as well as to the

expected slowing of SAN rate, suggesting a previously unsuspected role of HCN4 in AV node activity and stimulus conduction (Baruscotti et al., 2011). Finally, ectopic beats originating in pulmonary veins are recognized sources of atrial arrhythmias and can initiate AF. It is interesting to note that funny channel-expressing pacemaker cells are present in pulmonary veins, and can contribute to ectopic beat generation and arrhythmogenesis (Chen et al., 2009). This implies that dysfunctional funny channels and/or altered If tissue distribution may also contribute to atrial arrhythmias and AF.
My talk will be devoted to review recent reports illustrating how candidate gene screening of the Hcn4 gene in families with arrhythmias has identified several causative HCN4 mutations in different types of rhythm disorders, and to discuss the perspective of future research in this area.

Modulation of atrioventricular node cell activity: endothelin-1 and acetyl-choline

S.C. Choisy[1], H. Cheng[1], G.L. Smith[2], A.F. James[1] and J.C. Hancox[1]

[1]Cardiovascular Research Laboratories, Bristol Heart Institute, School of Physiology and Pharmacology, University of Bristol, Bristol, UK and [2]Cardiovascular Physiology, University of Glasgow, Glasgow, UK

The activity of the atrioventricular node (AVN) is established to be modulated by the autonomic nervous system. By contrast, whilst receptors for the peptide hormone endothelin-1 (ET-1) are known to be present in the AVN (e.g. Molenaar et al, 1993), until recently there has been little information on ET-1 modulation of AVN electrophysiology. Accordingly, we have studied effects of ET-1 on rabbit AVN cellular electrophysiology (Choisy et al, 2012a). For this investigation, adult male New Zealand White rabbits were killed in accordance with UK Home Office legislation and AVN cells were isolated by enzymatic and mechanical dispersion. Whole-cell voltage-clamp was performed at 37ºC using a standard Tyrode's solution and K^+-based pipette solution (Choisy et al, 2012a). Application of 10 nM ET-1 to spontaneously active AVN cells led to a rapid cessation of spontaneous action potentials (APs), accompanied by a marked membrane potential hyperpolarization that partially 'relaxed' in the presence of ET-1 (Choisy et al, 2012a). Under voltage-clamp, ET-1 reduced L-type calcium current and rapid delayed rectifier K^+ current, whilst during hyperpolarising voltage steps it activated a tertiapin-Q (TQ; 300 nM) sensitive inwardly rectifying current with properties similar to the muscarinic (GIRK) K^+ current, $I_{K,ACh}$ (Choisy et al, 2012a). This response showed some time-dependent decline. When spontaneous APs were recorded in the presence of TQ, AP magnitude progressively declined and the maximum diastolic potential depolarised. Thus, in the absence of TQ, ET-1 activation of $I_{K,ACh}$ was the dominant response (Choisy et al, 2012a).
Since our results with ET-1 were suggestive of some time-dependent decline of ET-1 activated $I_{K,ACh}$, this phenomenon was studied further in experiments using either ET-1 (10 nM) or acetyl-choline (ACh; 1 μM or 100 nM), together with repetitive application of brief voltage-ramps (Choisy et al, 2012b). In these experiments, ACh application activated a large TQ-sensitive $I_{K,ACh}$ via M2 muscarinic receptors. This response showed rapid bi-exponential 'fade' (Choisy et al, 2012b). Comparative experiments with ET-1 using the same protocol demonstrated 'fade' of ET-1-activated $I_{K,ACh}$, though with a different (mono-exponential) time-course. 'Fade' rate did not correlate with initial response (i.e. K^+ flux) magnitude. Sequential application of ACh (1 μM) and ET-1 (10 nM) showed heterologous desensitization of the ET-1 response by ACh. These results suggest that ET-1 and ACh act on a common pool of GIRK channels and that $I_{K,ACh}$ 'fade' involves desensitization that may occur down-stream of receptor activation. Internal application of GDPβS (3 mM) to rabbit AVN cells via diffusion from the patch-pipette led to a reduction in the extent of desensitization of $I_{K,ACh}$, consistent with an involvement of the G-protein cycle in rapid 'fade' of $I_{K,ACh}$ (*cf* Leaney et al, 2004). 'Fade' of $I_{K,ACh}$ was also observed in AVN myocytes isolated from a difference species (C57BL6J mice).
Collectively, the results of these studies indicate that both ET-1 and ACh activate $I_{K,ACh}$ in AVN myocytes and that the response exhibits rapid desensitization. Some previous studies on anaesthetized dogs (Martin, 1983) and rabbit isolated atrial preparations (Salata and Jalife, 1985) have provided evidence for 'fade' of the response to vagal stimulation. Our findings raise the possibility that this may be attributable to desensitization-induced 'fade' of AVN $I_{K,ACh}$.

The future of medicine: putting the individual where she should be

H.V. Westerhoff

Synthetic Systems Biology, SILS, NISB, the University of Amsterdam, Amsterdam, Netherlands and Manchester Centre for Integrative Systems Biology, University of Manchester, Manchester, UK

Airplanes and motorways are repaired successfully when broken. Humans suffering from one of the many multifactorial diseases are rarely so; at best, their diseases are managed. Yet, mankind has been able to put a man onto the moon and to get him back healthily. It is not that we haven't spent the same amount of money towards understanding and finding cures for these diseases. And it is not that we are linearly progressing towards curing these diseases: most new publications add more issues than they resolve. Lack of progress may be due both to the excessive complexity of the topic at hand, to a crisis in the handling of information and communication in the life sciences and health care, and to a reluctance to see the forest for the trees.

By organizing the plethora of biomedical information into a new type of dynamic framework, more of the information that is acquired will work towards the understanding of health and disease. The basis of this framework will be a molecule based, structured model of the human. I will discuss the potential that Recon2, the March 2013 consensus reconstruction of genome-wide human metabolism, may already offer. Important here is the ready generation of millions of metabolic maps, one for each sequenced individual. I will also give examples of how conjunction of such a genomics driven approach with an equally individualized physiological approach may lead to new strategies of dealing with truly individualized medicine: differential network-based drug design, transcription clocks, drug detoxification and biomarkers thereof.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA253

Microvascular systems biology

S. Peirce

Biomedical Engineering, Univ. of Virginia, Charlottesville, VA, USA

The growth and adaptation of microvascular networks are essential processes in development, tissue homeostasis, and responses to disease. The signaling networks and cellular behaviors that underpin the establishment and remodeling of microvessels are complex, dynamic, and spatially heterogeneous. Computational modeling approaches have enabled otherwise intractably difficult experiments to be performed in silico with high throughput hypothesis testing and generation. Computational and mathematical models at nearly every relevant level of biological scale (gene-to-tissue) have offered new insights. Increasingly, multiscale models that bridge phenomena at one level of scale to another, have been created and deployed to understand how perturbations within and around individual cells in a tissue affect vessel structure and overall organization of the network. Close integration with in vitro or in vivo experimental analogs, typically afforded by endothelial cell culture models or various thin vascularized tissues in small animal models (e.g. retina, subcutaneous tissue, ear, thin muscles), facilitates model specification and independent validation. Collaborative partnerships, which are often highly interdisciplinary, have emerged to fuel linkages between different modeling approaches and close coupling of models with experiments. Our group has recently partnered with other modeling groups and with experimental biologists to develop a novel multiscale model of sprouting angiogenesis (Figure 1). We have coupled agent-based modeling (ABM) with receptor-ligand kinetics modeling to explore how signaling inputs from neighboring cells (e.g. NOTCH/Dll4) and extracellular cues (e.g. VEGF) coordinate capillary sprouting and microvascular network patterning. Cellular functions including mitosis, migration, and phenotype regulation are explicitly modeled in the ABM, while a coupled partial differential equations model predicts extracellular gradients of growth factor, as well as membrane-bound and soluble receptor-ligand binding in and around the cell membrane. We demonstrate that when key parameters that are impossible to measure empirically (e.g. extent of the VEGF gradient across the length of a single cell) are varied within certain ranges, our multiscale model can accurately predict locations of capillary sprout emergence from a parent vessel that are consistent with independent experimental observations obtained using the embryoid body model of vasculogenesis. Sensitivity analyses further suggest that initial geometry is key to determining the location of sprout initiation while chemotactic gradients principally govern the rate of sprout extension. As with any model — experimental or computational — the true test of its utility is the ability to uncover new understanding that advances the field. To this end, we are deploying our multiscale model in an iterative model-experiment-model cycle in order to probe the fundamental mechanisms of sprout initiation, extension, maturation, and network patterning in the context of sprouting angiogenesis.

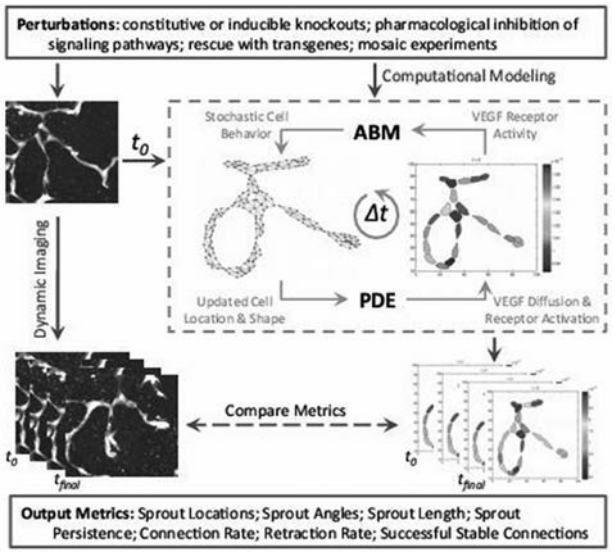

Figure 1. Multiscale computational model of capillary angiogenesis combines agent-based modeling with partial differential equations modeling to predict sprout emergence, extension, and connection. Confocal images of early-stage embryoid body networks specify the initial network configuration for the computational model at t=0. Quantitative analysis of dynamic images at subsequent time points provides independent validation for in silico predictions of emergent patterning outcomes. SA254

Multi-scale modeling of cardiac excitation-contraction coupling

N. Smith, S.A. Niederer, J. Lee, D. Nordsletten and P. Lamata

King's College London, London, UK

The diversity and quantity of currently available experimental and imaging data, including measurements of single cells, cardiac wall motion, chamber flow patterns, coronary perfusion and electrical mapping, presents a significant opportunity to improve both physiological understanding and ultimately clinical care for cardiovascular disease.

However, the clinical practice of using population-based metrics derived from separate image sets often indicates contradictory treatment plans due to both a lack of integrative mechanistic understanding and inter-individual variability in pathophysiology. Thus, despite measurement advances, determining optimal treatment strategies for cardiac patients remains problematic. To exploit the full value of measurement technologies, and the combined information content they produce, requires the ability to integrate multiple types of anatomical and functional data into a consistent framework.

An exciting and highly promising strategy for contributing to this integration is through the development of bio-physically based mathematical models. However, despite these advances there remains a significant translational barrier to applying and customising models to interpret specific experimental data or for human clinical application. This is because the vast majority of cardiac models are currently developed and validated using data collected from heterogeneous measurements in animal populations. These models are useful for the demonstration of proof of concept function and development of mechanistic concepts. However, there are inherent limitations to such model developments specifically with respect to quantitatively mimicking function in health and disease. Moreover, the relevance of insights gained from such models to human health remains difficult to determine.

To address these issues, we present recent developments in both murine and clinically relevant human models that cover the coupling and simulation of cardiac fluid flow, mechanics, perfusion and electrical excitation.

Modeling the pulmonary physiome: integration of clinical data with multi-scale analysis

M. Tawhai

Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

Achieving effective gas exchange in the mammalian lung requires coordinated matching of ventilation and perfusion, both of which are sensitive to the branching structure of the lung's airway and vascular trees, hydrostatic pressure, and gravity acting to deform the lung within the chest wall. Virtually all pathology of the lung impairs gas exchange by disrupting ventilation-perfusion (V/Q) matching, but because of the complexity of the integrated respiratory system it is not always possible to predict how impairment to a single mechanism will affect the function of the system as a whole. To understand the emergence of asthmatic bronchoconstriction and variable patient response to acute pulmonary embolism (APE) we have developed computational methods that exploit

volumetric computed tomography – from normal volunteers, clinical subjects with suspected APE, and animal validation studies – and pulmonary function testing, to derive structure-based models for predicting function in the individual. These data-driven multi-scale models include the pathways for ventilation and perfusion and their interaction at the gas exchange surface, and calcium signaling for smooth muscle force development. Multi-scale analysis reveals synergistic interactions between deep inspirations and smooth muscle fluidization during bronchoconstriction, which may contribute to different responses in normals and asthmatics; and that the cardio-respiratory response to mitigate hypoxia in APE is dependent on the location of embolus, with our model predicting V/Q disruption in regions that are distant from the embolus, and the severity of predicted response tightly correlated with clinically identified right ventricular dysfunction.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA256

Stochastic multiscale modelling of the neuro-musculoskeletal system

M. Viceconti

INSIGNEO Institute for in silico medicine, University of Sheffield, Sheffield, UK

Introduction

The socioeconomic burden imposed by osteoporosis is growing exponentially in every economically developed country [1]. The ability to predict subject at high risk of bone fracture is necessary to modulate the therapies but also to motivate necessary restrictions to the life style. Such risk is usually predicted with epidemiology-based models, the most popular being the FRAX system developed at the University of Sheffield. However, these models show in various studies limited predictive accuracy (expressed as area under the Receiver Operating Characteristic curve (AUC)), typically around 0.65 [2]. The primary reason for this moderate accuracy is that while the main cause of osteoporotic bone fractures is the loss of mechanical strength due to the increased porosity of bone tissue, another important cause is the tendency for elders to fall and overload the skeleton more frequently than normal healthy, a factor that can be modelled only as a stochastic process.

In the VPHOP project we developed a multiscale model of the neuromusculoskeletal system that can be individualised using patient data from clinical, imaging, and instrumental observation, capable of predicting the risk of bone fracture in a patient as a function of her degree of osteoporosis, of her propensity to fall, and of the expected progression of the disease over time without or with pharmacological treatment.

In this work we present such multiscale model, describe its current limitations, and show how a subset of it was validated over multiple restrospective cohorts, and confirmed with population studies.

Materials and methods

A complete body-organ-tissue-cell multiscale model of the skeletal biomechanics for the prediction of the hip and spine fractures have been realised by the VPHOP consortium, along the lines proposed in [3]. The multiscale model describes the skeletal loading as a stochastic process identified over a large database of musculo-articular forces during physiological and pathological activities, as predicted by an individualised whole body musculoskeletal dynamics model. Such loading spectra are applied, within a Monte Carlo scheme, to a individualised finite element model of the hip and of the spine, which predicts for each load instance if the bone would fracture or not in that condition; since those skeletal sites under those loading conditions fail both in fragile and ductile mode, a full anisotropic elastic-viscoplastic constitute equation was used. The bone constitutive equation is defined at the tissue scale, and homogenised at the continuum level. A bone-remodelling algorithm predicts the changes over time of the tissue morphology due to the cellular activity, which change the constitutive equation, and thus the strength of the bone.

The full multiscale model required 62,055 core hours to be solved, which makes it unpractical for large scale clinical use at this point in time. While we expect that in five years the computational cost will be reduced on 20 times only with the improvement of the computational resources, at the present it was decided to conduct the clinical validation using a subset of the multiscale model. This reduced model retrains the body and organ models, uses a linear-elastic failure criterion (accurate for the fragile fractures observed at the hip), and replace the tissue-cell models, with a phenomenological model that predicts the changes of the bone density at the continuum level as a function of time, removing the need to solve repeatedly tissue-scale finite element models involving over 20 million degrees of freedom.

Results

Various retrospective cohorts were investigated to assess the predictive accuracy of the reduced multiscale model. Here we present the results on a cohort originally investigated at the University of Sheffield, formed by 50 post-menopause women with a femoral neck fracture, and 50 non-fractured post-menopause women age, height, and weight matched. On this cohort the FRAX algorithm showed an AUC of 0.64, whereas the VPHOP model showed an AUC of 0.75, an improvement usually considered sufficient enough to justify the adoption of a new technology in the clinical practice. Comparable results were obtained in other studies conducted by our consortium, over two additional retrospective cohorts in Reykjavik and in Bologna.

In order to obtain a confirmation, the same multiscale model was used to conduct three public health studies where entire populations were modelled, using statistical distributions of input values derived from the literature for the specific population being modelled. In all three cases good agreement was found [4-6].

Regulators of spine density as targets for the treatment of psychiatric disease

M. Milenkovic, C. Mielnik, R. Ruddy and A. Ramsey

Pharmacology and Toxicology, University of Toronto, Toronto, ON, Canada

There is a growing body of literature correlating changes in spine density and morphology with changes in brain function and behavior. Altered spine density has been reported in many disease states including schizophrenia and depression. Therefore, spine density could be a useful index to measure the therapeutic profile of psychoactive drugs. In the same way, the signal transduction systems that induce synaptogenesis and maintain spine density represent promising targets for the development of new treatments for mental illness.
Our laboratory has studied the role of the NMDA-type glutamate receptor in the regulation of spine density, with a focus on the mechanisms by which altered spine density could translate into psychiatric disease states. NMDA receptors have been implicated in a number of psychiatric diseases as a causal agent or a target for therapeutic intervention. For example, NMDA receptor hypofunction is thought to contribute to the symptoms of schizophrenia, a disease in which reductions in spine density have been reported. Using a genetic mouse model, we have discovered that sustained NMDA receptor dysfunction causes an age-dependent reduction in spine density. Our findings show that NMDA receptor signaling is more important for synapse maintenance than synapse formation. Furthermore we found a temporal developmental correlation between spine loss and several behavioral abnormalities. We sought to determine the molecular mechanisms by which NMDA receptor dysfunction leads to spine loss. Our investigation revealed reductions in the levels of the Rho GTPase Rac1 and its downstream effectors. Therefore, RhoGTPase signaling represents a novel pathway to modulate spine density and improve psychiatric conditions.

Synaptic signaling scaffolds and autism spectrum disorders

E. Kim

Center for Synaptic Brain Dysfunctions, Institute for Basic Science (IBS), Daejeon, Republic of Korea and Department of Biological Sciences, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Republic of Korea

A growing number of synaptic proteins have recently been associated with diverse neuropsychiatric disorders including autism spectrum disorders (ASDs), schizophrenia, attention deficit hyperactivity disorder (ADHD), and mood disorders. ASDs represent a group of neurodevelopmental disorders with a prevalence of ~1% and are characterized by core symptoms including impaired social interaction, impaired social communication, and restricted/repetitive behaviors and interests. Although a large number of ASD-related genes and mutations have been identified, a few of them have been verified by approaches including mouse genetics. In addition, neural mechanisms underlying the development of ASDs remain largely unknown, explaining the lack of efficient medications for the treatment of autism. Synaptic scaffolding proteins at excitatory synapses interact with various synaptic proteins including receptors and signaling molecules, and promote the physical and functional coupling of receptor activation with downstream signaling events. In this presentation, I will discuss how defects in synaptic signaling scaffolds affect synaptic transmission, signaling, and plasticity, and how these defects are associated with ASD-like behavioral abnormalities in mice.

Glutamate receptor surface dynamics: regulation in brain pathophysiology

L. Groc

CNRS - Université de Bordeaux, Bordeaux, France

Glutamate, the major excitatory neurotransmitter in brain, activates diverse subtypes of receptors. The NMDA receptor type (NMDAR) play critical roles in both synaptic integration and plasticity. The subunit composition of these receptors, typically GluN2A and/or GluN2B containing, is controlled both by development and activity. This composition plays a crucial role in fine-tuning receptor function. Recent studies have made substantial progress in understanding the cellular and molecular underpinnings of the dynamic behavior of glutamate receptors such as NMDAR and their role in disease. Using high-resolution nanoparticle imaging we recently track single NMDAR at the surface of live neurons. This revealed that the surface distribution and dynamics of NMDAR is locally regulated by salient neuronal stimulation and, interestingly, such surface trafficking plays an instrumental role in synaptic adaptations. In models of neuropsychiatric disorders, characterised by a known altered glutamate transmission, we uncovered an altered surface dynamics of the glutamate receptors (e.g. NMDAR), opening new avenues of research for our comprehension of the glutamate receptor dysfunction in brain diseases and for future therapeutical strategies.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Effect of disease causing mutations on NMDA receptor function

H. Yuan[1], T. Pierson[3], S. Undiagnosed Disease Program[2] and S.F. Traynelis[1]

[1]Pharmacology, Emory University School of Medicine, Atlanta, GA, USA, [2]Undiagnosed Disease Program, NIH, Bethesda, MD, USA and [3]Pediatrics and Neurology, Cedars-Sinai Medical School, Los Angeles, CA, USA

NMDA receptors are ligand-gated cation-selective channels that mediate a slow, Ca2+-permeable component of the excitatory postsynaptic current. These receptors are involved in a wide range of important functions in the central nervous system, including synaptic plasticity and development. In addition, these receptors have been implicated in several neurological diseases, including depression, schizophrenia, Parkinson's disease, and epilepsy. We have, in collaboration with the NIH Undiagnosed Disease Program, investigated de novo mutations that have been found to arise in patients with varying neurological disorders, including seizures or developmental delay. Next generation high throughput whole exome sequencing of patients, parents, and relatives together with unique de novo analysis routines has identified a single candidate mutation within NMDA receptor subunits GRIN2A and GRIN2B for each patient. These mutations were subsequently introduced into recombinant human NMDA receptor cDNAs encoding the GluN2A and GluN2B subunits, which were studied in heterologous expressions systems using voltage clamp recordings to assess their effects on channel function. We utilized two electrode voltage recordings from Xenopus laevis oocytes injected with cRNA transcribed in vitro to study pharmacological properties of mutant human GluN1/GluN2 NMDA receptors. These experiments were complemented with patch clamp recordings in HEK 293 cells transfected with cDNA encoding the human GluN1/GluN2 NMDA receptor subunits. The goal of these functional studies was to determine whether the changes in receptor properties produced by these mutations were potentially disease-causing. In both cases the mutations had strong functional effects that were highly suggestive of these mutations being disease-causing. The location of the mutation implicated a key residue in the glutamate binding domain of GluN2B and S2-M4 GluN2A linker. The loss of function GluN2B mutation showed dramatically lower sensitivity to glutamate (50-fold higher EC50) without a change in glycine potency, and was associated clinically with severe developmental delay. The GluN2A gain-of-function mutation increased both glutamate and glycine potency 8-fold and increased open probability, leading to hyperactive NMDA receptors. The overactivation of NMDA receptors may account for frequent seizures. Experiments with memantine showed that it remained an effective antagonist against mutant NMDA receptors, suggesting a therapeutic course of action, which when implemented improved the patient's condition. We are currently expanding our search for potential disease causing mutations in the glutamate receptor family. Identification and characterization of such mutations provides an opportunity both to better understand glutamate receptor function, as well as the role of glutamate receptors in human disease.

Computations performed by theta LFP oscillations in the hippocampal formation

J. O'Keefe

University College London, London, UK

The rodent hippocampal formation constructs a spatial representation of the local environment which can be used to identify the animal's current location, to remember events that happened there in the past, and to navigate to desirable locations in that environment. Spatial cells found in the hippocampal formation represent the animal's location (place cells), its current heading direction (head direction cells), the metric of the environment (grid cells), and the animal's distance from boundaries of the environment (boundary vector cells). These cells provide two ways of identifying the animal's location, first on the basis of its relationship to environmental landmarks, and second on the basis of path integration signals which update this location on the basis of interoceptive cues from the vestibular, proprioceptive and motor systems. All of the cells use firing rate as the code for spatial representation. In addition, however place and grid cells use a timing code. This timing code takes the form of the phase of spike firing relative to the ongoing theta - local field potential (LFP) wave. The sinusoidal theta rhythm is a prominent feature of the hippocampal LFP which ranges between 6 - 11 Hz in the rat, the rate varying as a function of the animal's running speed. We have suggested that theta-LFP is an integral part of one of the mechanisms by which the hippocampus carries out spatial computations. A key idea here is that there is not one but several theta -like oscillations of differing frequencies which produce oscillatory interference patterns which can account for many of the properties of place and grid cell firing. I will describe these ideas and discuss recent experiments which provide evidence in favour of and against them.

Network dynamics in entorhino-hippocampal circuits during exploratory behaviour

A. Sirota

Center for Integrative Neuroscience, University of Tuebingen, Tuebingen, Germany

Population representation of spatial memories in hippocampus exhibits complex spatio-temporal dynamics. It is likely that understanding mechanistic origin of this dynamics and link to animal behaviour is the key to understanding the code. To this end we investigate the role of gamma synchronization dynamics across entorhino-hippocampal system and ongoing exploratory behaviour of the rat as dynamics contributors to the population coding in hippocampus. We show how dynamic changes in gamma synchronization and exploratory behaviour affect hippocampal activity.

Cell-type specific regulation of hippocampal microcircuits

I. Soltesz

Anatomy & Neurobiology, University of California Irvine, Irvine, CA, USA

Distinct interneuronal subtypes have evolved in cortical circuits to deliver GABA to specific spatial domains of principal cells at particular times during behaviorally relevant network oscillations. The precise spatiotemporal control of populations of principal cells by the GABAergic system is a critically important yet incompletely understood process that is compromised in several other major neurological and psychiatric disorders. A significant gap in our understanding of the GABAergic control of chronocircuits has been the lack of precise information about the interneuronal firing patterns during network oscillations in the anesthesia-free brain. We will discuss recent results from awake, head-restrained animals that demonstrate the differential, highly specific spike timing of perisomatic and dendritically projecting, rigorously identified hippocampal interneuronal subtypes during theta, gamma, epsilon and ripple oscillations. The results reveal a novel form of frequency-independent temporal ordering of interneuronal discharges during network oscillations in the hippocampus. In addition, we will also discuss how the close integration of experimental findings with large-scale, data-driven computational simulations of hippocampal networks offers a powerful tool towards the identification of key circuit parameters that may be particularly effective in controlling chronocircuit behavior. These closely integrated experimental and computational approaches allows a better understanding of the mechanisms underlying neuronal oscillatory circuit functions in control animals and chronocircuit dysfunction in neurological and psychiatric disorders.

Optogenetic dissection of oscillatory circuits

I. Oren[1,2], M. Cano-Jaimez[2] and D.M. Kullmann[2]

[1]Centre for Cognitive and Neural Systems, University of Edinburgh, Edinburgh, UK and [2]Department of Clinical and Experimental Epilepsy, UCL Institute of Neurology, London, UK

The hippocampal CA1 network supports gamma oscillations of variable frequencies, with fast (~80Hz) and slow (~40Hz) gamma occurring on different phases of the theta cycle (Colgin et al., 2009). It has been suggested that the fast and slow components are generated through distinct excitatory pathways, namely, perforant path and Schaffer collaterals respectively. However, the functional local circuitry that is recruited by the inputs to generate these gamma frequency bands remains to be determined.
In order to investigate the local circuit mechanisms of oscillatory responses to variable excitatory drive, we induced oscillations in acute hippocampal slices in vitro. Mice (3 weeks) were transfected with the red-shifted depolarising opsin C1V1 (Yizhar et al., 2009) by stereotactic intrahippocampal injection (under isofluorane anaesthesia) of an adeno-associated virus with a Camk2α promoter. The virus was left to express for 4 weeks. Mice were sacrificed by transcardial perfusion with an N-Methyl-D-Glucamine based saline solution and acute horizontal slices prepared. We delivered variable intensity ramps of light to slices and simultaneously recorded the local field potential and whole-cell intracellular currents.
Light ramps induced gamma frequency oscillations in the CA1 pyramidal cell layer (range=34 – 51 ±2 Hz, n=5. Means ± SEM. Recorded at 32^{o}C). Phasic excitatory and inhibitory synaptic currents occurred in both principal cells and interneurons. Synaptic currents were superimposed on a direct C1V1-mediated current that was prominent in pyramidal neurons. Blocking glutamatergic synaptic transmission profoundly attenuated oscillations. Increasing the drive to the network increased oscillation frequency, and shifted the oscillation from an inhibition-dominant to an excitation-dominant regime.
These findings suggest that differential recruitment of pyramidal cells and interneurons by CA1 afferents may contribute to the emergence of fast and slow gamma in vivo.

SA265

Cortical properties of human slow wave sleep

I. Ulbert

RCNS HAS, Budapest, Hungary

The slow wave is a fundamental cortical rhythm that emerges in deep non rapid eye movement sleep. It is thought to underlie essential restorative processes and facilitate the consolidation of declarative memories. Animal studies show that slow wave activity is composed of rhythmically recurring phases of widespread, increased cortical cellular and synaptic activity, referred to as active- or up-state, followed by cellular and synaptic inactivation, referred to as silent- or down-state. However, its neural mechanisms in humans are poorly understood. To elucidate the intracortical neuronal mechanisms of slow wave activity in humans, laminar microelectrodes were chronically implanted into the cortex of patients with focal epilepsy undergoing cortical mapping for seizure focus localization.
We found that slow wave activity in humans reflects a rhythmic oscillation between widespread cortical activation and silence. Cortical activation was demonstrated as increased wideband spectral power including virtually all bands of cortical oscillations, increased multiple and single unit activity, and powerful inward trans-membrane currents, mainly localized to the supragranular layers. Neuronal firing in the up-state was sparse and the average discharge rate of single cells was less than expected from animal studies. Action potentials at up-state onset were closely synchronized across all cortical layers, suggesting that any layer could initiate firing at up-state onset.
These findings provide experimental evidence that slow wave activity in humans is characterized by hyperpolarizing currents associated with suppressed cell firing, alternating with high levels of oscillatory synaptic/trans-membrane activity associated with increased cell firing. Our finding that slow wave activ-

ity and corresponding high frequency rhythms including spindle, alpha, beta, gamma and ripple oscillations mainly involve supragranular layers is consistent with the massive cortical expansion of neuronal number and increased apical dendritic complexity observed in humans.
The strong supragranular oscillatory activity in sleep may be beneficial for the local, higher order processing of previous sensory experience, since these layers are interconnected by dense cortico-cortical projections forming fine-scale functional networks to perform integrative functions. The weaker infragranular activity may reflect the relatively suppressed cortical executive, output functions, which may prevent effective connectivity between distant cortical areas from developing in slow wave sleep.

SA266

The efferent olivocochlear system and protection from acoustic trauma

A.B. Elgoyhen

Institute for Research in Genetic Engineering and Molecular Biology, CONICET, Buenos Aires, Argentina

Sound-induced acoustic injury is one of the most common causes of hearing loss and tinnitus. Although prevention from exposure to intense sound would be the obvious way to keep our inner ear healthy, finding alternatives to increase resistance to damage is a research field of great interest. The medial olivocochlear (MOC) pathway provides inhibitory feedback, through the release of acetylcholine (ACh) from brainstem neurons onto outer hair cells (OHCs) of the cochlea, reducing their ability to amplify sounds, and thus reducing cochlear sensitivity. Although many possible roles for this pathway have been proposed, understanding remains incomplete. We have explored the MOC pathway's function by generating a strain of genetically modified mice carrying a mutation in the nicotinic acetylcholine receptor (nAChR) subunit expressed by OHCs. We tested the effect of the mutation by recording signals from hair cells in cochlear preparations in vitro. Mutant hair cells exhibited greater sensitivity to exogenous ACh and the synaptic currents were prolonged in comparison to wild type preparations, indicating that the mutation enhanced nAChR function. To determine the consequences of this enhanced receptor function for cochlear responses, we measured auditory brainstem responses and distortion product otoacoustic emissions. The threshold levels of sound required to evoke these responses were elevated in the mutant mice, suggesting that the baseline inhibitory effect of the MOC pathway was enhanced. Furthermore, suppression of OHC-mediated amplification produced by stimulating the MOC pathway electrically was enhanced and dramatically prolonged in mutant mice. Surprisingly, mutant mice had a greater resistance to permanent acoustic injury resulting from exposure to 100 dB sounds, indicating that activation of the MOC feedback can protect the inner ear from noise-induced damage. Thus, the efferent pathway provides a promising target for pharmacological prevention of inner ear pathologies derived from acoustic injury, such as hearing loss and tinnitus. Finding drugs that mimic the effect of the mutation would be the developmental path to follow.

Effect of myelin loss on synaptic function in the auditory brainstem

S. Kim[1], C. Kushmerick[2] and J. Kim[1]

[1]Department of Physiology, University of Texas Health Science Center, San Antonio, TX, USA and [2]Departamento de Fisiologia e Biofisica, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil

Myelination of axons greatly increases the conduction velocity and fidelity of impulse propagation in the mammalian CNS. The auditory brainstem is a useful model to test the importance of proper myelination because its circuits rely on very fast, precise, and reliable synaptic relays to process auditory information. To determine the fundamental role of myelination in auditory brainstem function, we recorded the sound evoked auditory brainstem response (ABR) from Long Evans Shaker (LES) rats, which lack myelin due to a genetic deletion of myelin basic protein. Control and LES rats were anesthetized and maintained with 2 % isoflurane (1 L/min O2 flow rate) during ABR recording. In control, the ABR evoked by a click consisted of five well-defined waves (denoted wave I-V), whereas in LES rats waves II and III could not be distinguished and the latency to wave I and IV was greatly increased. In addition, the sound threshold of the ABR was increased in LES rats using tone stimulations of 8 kHz or higher. The central conduction time of the auditory pathway increased significantly in the LES rats, while control showed a significant reduction of conduction time during development. To identify mechanisms by which central demyelination impairs the transmission of auditory signals, alterations in synaptic transmission were explored using whole-cell patch clamp at the synapse formed by the calyx of Held nerve terminal in the Medial Nucleus of the Trapezoid Body (MNTB) in the auditory brainstem. In LES rats, postsynaptic neurons from the MNTB displayed a delayed action potential and an increase in the number of action potential failures during high frequency stimulation when compared to controls. Voltage clamp experiments revealed that the size of the EPSC and the degree of EPSC depression during high frequency stimulation was similar in control and LES MNTB, but both the conduction delay and the synaptic delay were increased in LES rats. Taken together our results suggest that the defects observed in evoked auditory potentials in LES rats is related to the reduction in the temporal fidelity and the reliability of synaptic transmission, which is critical for the accurate processing of sound signals in auditory brainstem involved in sound localization.

Cellular mechanism of sound localization

M. van der Heijden[1], J.A. Lorteije[1,3], A. Plauska[1], M.T. Roberts[2], N.L. Golding[2] and J.G. Borst[1]

[1]Neuroscience, Erasmus MC, Rotterdam, Netherlands, [2]Section of Neurobiology and Center for Learning and Memory, University of Texas at Austin, Austin, TX, USA and [3]Vision & Cognition, Netherlands Institute for Neuroscience, Amsterdam, Netherlands

Neurons in the medial superior olive (MSO) enable sound localization by their remarkable sensitivity to submillisecond interaural time differences (ITDs). Each MSO neuron has its own "best ITD" to which it responds optimally. A difference in physical path length of the excitatory inputs from both ears cannot fully account for the ITD tuning of MSO neurons. As a result, it is still debated how these inputs interact and whether the segregation of inputs to opposite dendrites, well-timed synaptic inhibition, or asymmetries in synaptic potentials or cellular morphology further optimize coincidence detection or ITD tuning. Using in vivo juxtacellular and whole-cell recordings, we find that ITD tuning of MSO neurons is determined by the timing of their excitatory inputs. The inputs from both ears sum linearly, whereas spike probability depended nonlinearly on the size of synaptic inputs. This simple coincidence detection scheme thus makes accurate sound localization possible.

What does a cochlear implant do to your brain? Plastic changes in the primary auditory cortex with long-term deafness and cochlear implant use

J.B. Fallon

Bionics Institute, East Melbourne, VIC, Australia and University of Melbourne, Melbourne, VIC, Australia

Sensorineural hearing loss initiates a cascade of anatomical and functional changes within the auditory system. The secondary loss of spiral ganglion neurones, the target cells of cochlear implants, is the most critical peripheral change; and there are a range of atrophic changes within the central auditory pathway. However, equally important are the functional changes, particularly the degradation in spatial (spectral) and temporal processing, that occur within the central auditory system.

Over the past decade, we have focussed on the changes in the response of the primary auditory cortex in the cat to intracochlear electrical stimulation with long-term, ototoxically induced, profound deafness. The most striking effect is a complete loss of the normal cochleotopic organisation seen in normal hearing animals. We have also examined the effects of chronic environmentally derived intracochlear electrical stimulation, delivered by a cochlear implant, on central auditory processing. Specifically, chronic cochlear implant use can drive the cochleotopic organisation of primary auditory cortex, both in young and mature animals. The effects of cochlear implant use can be observed after as little as one month of chronic use, highlighting the importance of early (re)habilitation following implant activation in a clinical setting.

The excellent performance of cochlear implant recipients has also led to a relaxation of the criteria for candidacy for implantation. Initially only implanted in patients with no useful hearing in either ear, patients with significant amounts of low-frequency hearing are now routinely implanted, who previously would only have been treated with hearing aids. These patients have access to information from both acoustic hearing (via their remaining low-frequency hearing) and electric hearing (via their cochlear implant stimulating the more basal, high frequency region of the cochlea). However, it is unclear how the central auditory system represents and integrates the two modalities of stimulation. Therefore, we have begun examining the representation of both acoustic and electric activation of the cochlea in ototoxically partially deafened animals, some of whom have received a cochlear implant.

This work was funded by NIDCD (HHS-N-263-2007-00053-C) and the NHMRC (1002430). The Bionics Institute acknowledges the support it receives from the Victorian Government through its Operational Infrastructure Support Program.

Optimizing VNS-directed neural plasticity for the treatment of chronic tinnitus

M. Kilgard[1], M. Borland[1], P. Beall[1], E. Buell[1], S. Vanneste[2,1], D. De Ridder[2], A. Sloan[1] and R. Rennaker[1]

[1]Behavioral and Brain Sciences, University of Texas at Dallas, Richardson, TX, USA and [2]University Hospital, Antwerp, Belgium

Pathological neural plasticity plays a major role in the genesis and maintenance of chronic tinnitus. Reversal of aberrant plasticity is therefore a promising approach to the treatment of tinnitus.We have developed a novel method to direct highly specific and long lasting neural plasticity (Engineer, 2011). Brief bursts of vagus nerve stimulation (VNS) trigger release of neuromodulators that direct brain changes specific to associated neural activity patterns. Pairing VNS with tones is sufficient to powerfully shape responses in the central auditory system. We have demonstrated that this therapy can be therapeutic in an animal model of tinnitus and in human patients. We are now optimizing the clinical parameters through parallel studies in humans and preclinical studies in animals. We will present evidence suggesting that with further study VNS-directed plasticity may be optimized to become a reliable, safe, and long-lasting therapy for chronic tinnitus.

Ghrelin: an orexigenic gut - brain reward signal

S.L. Dickson, R.H. Shirazi and K.P. Skibicka

Institute of neuroscience and Physiology, The Sahlgrenska Academy at the University of Gothenburg, Gothenburg, Sweden

Obesity has reached global epidemic proportions and there is therefore much need to understand mechanisms underlying excessive and uncontrolled food intake. Ghrelin, the only known circulating orexigenic hormone, stimulates feeding behavior via its CNS actions. In addition to its role in "metabolic hunger", ghrelin potently increases food reward behavior (1,2). The neurochemical circuitry that links ghrelin to the mesolimbic reward system and to the increased food reward behavior remains unclear (3). Ghrelin receptors can be found on the ventral tegmental area (VTA) dopamine neurons (4) and ghrelin injection to the VTA is sufficient to drive food motivated behavior (5). It is, however, unknown which dopaminergic projections are relevant for ghrelin's effects on reward, since VTA dopamine neurons send projections to several brain areas relevant for reward behavior including the nucleus accumbens (NAc), amygdala and prefrontal cortex. Here we examine whether VTA-NAc dopaminergic signalling is required for the effects of ghrelin on food reward and intake. To measure food motivation/reward behavior, rats were trained in a progressive ratio sugar-induced operant behavior schedule. Chow intake was measured subsequent to the operant behavior test. A D1-like or a D2 receptor antagonist was injected into the NAc in combination with ghrelin microinjection into the VTA to investigate whether this blockade attenuates ghrelin-induced food reward behavior. VTA injection of ghrelin significantly increased food reward behavior and chow intake. Pretreatment with either a D1-like or D2 receptor antagonist into the NAc, completely blocked the reward effect of ghrelin, leaving chow intake intact. We also found that this circuit is potentially relevant for the effects of endogenously released ghrelin as both antagonists reduced fasting (a state of high circulating levels of ghrelin) elevated sucrose-motivated behavior but not chow hyperphagia. Taken together our data identify the VTA to NAc dopaminergic projections, along with D1-like and D2 receptors in the NAc, as essential elements of the ghrelin-responsive circuits controlling food reward behavior. Interestingly the results also suggest that food reward behavior and the intake of chow are controlled by divergent circuitry, where NAc dopamine plays an important role in food reward but not in food intake. The idea that ghrelin's effects on food intake and food reward behavior engage different reward circuitry is also supported by previous studies in which we were able to parse ghrelin's effects these behaviors pharmacologically using mu-preferring opioid receptor antagonist or an NPY Y1 receptor antagonist (6).

SA272

Reciprocal interactions between the stress response and hedonic food reward after prenatal stress

J. Menzies

University of Edinburgh, Edinburgh, UK

Stress can increase or decrease food intake and, consequently, body weight. However, in animal models of stress, rats often selectively increase palatable high-energy food intake and put on weight. There is a parallel in human behaviour – comfort eating, a widespread behaviour where people who feel anxious or stressed seem motivated to consume palatable food. The mechanisms underlying this stress-induced change in behaviour are unknown. Here we use a model of prenatal stress in rats to examine palatable food consumption and the reciprocal effect of palatable food rewards on the acute stress response.

Prenatally stressed (PNS) rats were generated by exposing their mothers to repeated social stress during the latter part of pregnancy. These rats show an enhanced acute stress response as adults, reflected in increased plasma levels of ACTH and corticosterone (CORT; Brunton and Russell, 2010). We hypothesised that this enhanced acute stress response could be suppressed by consumption of palatable high-energy food prior to the acute stressor. To test this we gave a group of PNS rats twice-daily time-restricted access to a condensed milk reward for 14 days and monitored their feeding behaviour (n = 7). A group of unrewarded PNS rats (n = 7) and two groups of control rats (one rewarded, one unrewarded, both n = 8) acted as comparisons.

Both PNS and control rats quickly learned to consume the reward in the allotted time. In control rats the latency to start eating had reduced from 237±66 sec (mean±sem) to 16±3 sec by day 4. However, the latency in PNS rats remained high and variable (233±154 sec on day one, 76±31 sec on day 14) indicating that PNS rats may have a reduced motivation to consume rewarding foods. Next we tested the effect of reward access on the acute stress response. At the end of the reward period all rats were subjected to a 30 min acute restraint and blood was taken before, during and after to measure plasma CORT by RIA. All rats showed an increase in CORT during the

restraint stress that returned to baseline levels 4 h after the stress. Unrewarded PNS rats showed an enhanced stress response compared to unrewarded control rats. Rewarded PNS rats showed an increased stress response compared to unrewarded PNS rats, though this increase was superimposed on a higher baseline CORT secretion after reward consumption. Moreover, access to reward appeared to reduce the duration of the CORT response in control but not PNS rats. Hence, intake of palatable food can influence the HPA axis response to acute stress.

In vivo neural responses to changes in energy balance, leptin and ghrelin

G. Van der Plasse, R. van Zessen, M. Luiendijk, G. Ramakers and R. Adan

UMCU, Utrecht, Netherlands

The mesolimbic dopamine (mesDA) system is known for its role in associative learning, reward-seeking, and signaling of reward-related information. As such, increased activity of mesDA neurons drives motivated behavior and promotes operant responding for food. What remains unclear is the nature of mesDA's role in energy balance. Given the fact that ventral tegmental area (VTA) dopamine (DA) neurons are sensitive to feeding-hormones like leptin and ghrelin (that signal information about the current metabolic state), this system may be important in the regulation of food intake.
To investigate how energy balance affects reward-signaling by mesDA neurons, in vivo electrophysiological recordings were made of (putative) DA neurons in the ventral tegmental area (VTA) during the execution of a behavioural task. Neuronal activity was subsequently related to cue-presentation and the delivery of food rewards. To manipulate energy balance, animals were either food-deprived or free-fed preceding the recording session. In addition, the effect of peripheral injections of leptin and ghrelin on reward-encoding was measured. Elucidation of how hunger, leptin and ghrelin signaling affect mesDA neurons in feeding behavior provides important insights into the role of this neural circuit in obesity and anorexia nervosa

Dissecting the neural and behavioral processes linking leptin and reward

S. Fulton

Nutrition, University of Montreal, Montreal, QC, Canada and Montreal Diabetes Research Center, Montreal, QC, Canada

The adiposity hormone leptin is a critical modulator of energy balance. Apart from its hypothalamic actions, leptin regulates neural circuits controlling reward, motivation and emotion. Leptin has been shown to inhibit motivated behavior for rewarding electrical brain stimulation and palatable food. Dopamine (DA) neurons of the midbrain ventral tegmental area (VTA) are an essential component of the neural circuitry regulating motivation and reward. Via the long-form of its receptor (LepRb) leptin targets the VTA to inhibit feeding, food-motivated behavior, locomotion, and anxiety. Stat3 is the predominant signal whereby leptin regulates gene expression and leptin induces Stat3 phosphorylation in dopamine (DA) and GABA neurons of the VTA. We generated DA-specific Stat3 knockout (KO) mice to determine the contribution of LepRb-Stat3 signaling in midbrain DA neurons. While showing a similar anorectic response to leptin, KO mice exhibit marked impairments in food-motivated operant learning. In addition to large increases in ambulatory activity and voluntary running in male KO mice, the rewarding aftereffects of running are significantly elevated. These behavioral changes are accompanied by decreases in DA biosynthesis and D1 receptor protein expression in the nucleus accumbens. Our findings suggest an important role for leptin in attenuating running reward that are mediated via LepRb-Stat3 signaling in midbrain DA neurons and changes in DA tone. We posit that leptin acts in mesolimbic brain reward circuitry as a signal-of-plenty to dampen the motivational and rewarding effects of several behaviors that serve to replenish energy stores.

Opioid orchestration of feeding behavior

C. Dieguez

Department of Physiology, University of Santiago de Compostela, Santiago de Compostela, Spain

The relevance of opioids in reward processes leading to addictive behavior such as self-administration of opioids and drugs of abuse including nicotine and alcohol is widely recognized. Data gleaned in recent years have uncovered the importance of the endogenous opioid system modulating feeding behavior and other parameters that are crucial for the regulation of energy balance in both prelinical and clinical settings. The effects of endogenous opioid tone in food intake appears to be exerted by the three main families of opioid receptors. Data obtained from transgenic knockout mice for the different receptors subtypes indicates that the complete lack of MOR and KOR causes important alterations in energy balance, particularly when mice are fed on fat-enriched diets . Adminis-

tration of selective μ-agonists into the NAcc of rodents induces feeding even in satiated animals, while administration of μ-antagonists reduces food intake. Using pharmacological and gene silencing approaches, it was recently shown that ghrelin utilizes a hypothalamic κ-opioid receptor (KOR) pathway to increase food intake in rats. Pharmacological blockade of KOR decreases the acute orexigenic effect of ghrelin. Inhibition of KOR expression in the hypothalamic arcuate nucleus is sufficient to blunt ghrelin-induced food intake. By contrast, the specific inhibition of KOR expression in the ventral tegmental area does not affect central ghrelin-induced feeding. This new pathway is independent of ghrelin-induced AMP-activated protein kinase activation, but modulates the levels of the transcription factors and orexigenic neuropeptides triggered by ghrelin to finally stimulate feeding. These data implicate hypothalamic KOR signaling in the orexigenic action of ghrelin. Whether other orexigenic signals act through this pathway or whether this effect is specific for ghrelin is under investigation.

The "ins and outs" of Ca^{2+} sparks

M.B. Cannell

Physiology & Pharmacology, Bristol University, Bristol, UK

In cardiac muscle, depolarization of the sarcolemma initiates Ca2+ release by activating sarcolemmal L-type Ca2+ channels, providing a small increase in cytoplasmic calcium concentration in the junctional space of the dyad. This initiates [Ca2+]-dependent activation of the sarcoplasmic reticulum (SR) Ca2+ release channels known as ryanodine receptors (RyRs). The subsequent release of calcium from the SR further increases the [Ca2+] in the junctional space and leads to regenerative RyR activation, in a process called calcium-induced calcium release (CICR)(1). In such a regenerative process, the larger SR Ca2+ flux should prevent subsequent control by the surface membrane as well as SR Ca2+ store depletion. However, the quantity of Ca2+ released from the SR has a graded dependence on the magnitude of the Ca2+ influx across the sarcolemma and the SR releases only ~50% of its total content (e.g. (2)). The discovery of Ca2+ sparks (3) provided a solution to this problem by showing that graded responses can result from the spatio-temporal summation of individual Ca2+ release sites which are spatially uncoupled to limit regenerative behaviour. However, local regeneration in CICR during Ca2+ sparks might still prevent reliable Ca2+ spark termination.
Using computer modelling to recover the flux associated with a Ca2+ spark places limits on (for example) the number of RyRs involved in their generation as well as SR release time course. Our work shows that RyR closure appears to occur more slowly than the SR release flux, suggesting that local depletion of the SR store may be key to termination. In addition, by incorporating measured RyR gating (from planar lipid bilayer experiments) we find that the termination of SR release can be explained by a process we call induction decay(4). Induction decay provides robust termination of SR Ca2+ release because the falling RyR single channel current (as the local SR depletes) leads to a rapid increase in RyR closed time. This prevents RyRs reopening before an open RyR closes, thereby breaking the regenerative feedback during CICR. This is essentially the reversal of Ca2+ release inducing process within CICR (which prompted our naming it induction decay).
Therefore after 30 years of work, the mechanisms that activate and terminate Ca2+ sparks (and the whole cell Ca2+ transient) are gradually becoming clearer, although fine details such as the role of RyR gating modulation remain to be clarified. In addition, the possible remodelling of the junction between the surface membrane and SR in disease may also contribute to the development of dyssynchrony in Ca2+ release (e.g. 5). Recent developments in ultra high resolution imaging (e.g. 6) may provide the much needed structural information to explain such effects with more anatomically accurate computer models.

Subcellular alterations in RyR activation in a sheep model of atrial fibrillation

N. MacQuaide[1], I. Lenaerts[1], P. Holemans[1], R. Willems[2] and K.R. Sipido[1]

[1]Experimental Cardiology, Department of Cardiovascular Sciences, KU Leuven, Leuven, Belgium and [2]Cardiology, Department of Cardiovascular Sciences, KU Leuven, Leuven, Belgium

In sheep atrial myocytes, a moderate density of t-tubular structure has been described, which was further reduced as a result of remodeling in a model of atrial pacing induced persistent atrial fibrillation (AF). A concomitant reduction in ICaL and triggered Ca^{2+} release was observed, as well as attenuation of β-receptor responsiveness. In the current study, we have examined the effect of proximity of TTs to RyR on diastolic RyR activity (spontaneous Ca^{2+} sparks) and how this changes after induction of AF. The role of CaMKII in this situation is further investigated.
Ca^{2+} transients were recorded in fluo-4 loaded cells using confocal linescan microscopy (CLSM). Whole cell voltage clamp was used to elicit Ca^{2+} release induced by depolarizing pulses at 2Hz. 3-D distance mapping was used to correlate time to half maximal release of the fluorescence from triggered Ca^{2+} release with TT proximity. Release sites were localized and categorized as coupled (≤0.5 μm) and non-coupled (≥2 μm). After 2 minutes, stimulation was stopped and spontaneous Ca^{2+} sparks were measured for a period of 15 seconds and assigned to their cellular locations. SR content was assessed by integrating the sodium calcium exchange current after rapid application of caffeine (10 mM).
In CTRL myocytes (N=6, n=21), non-coupled sites regions had less frequent sparks (-32.7±11.1%) than coupled regions. These had similar amplitude and width, but the mean half-maximal duration was reduced by 16.5±7.8 %. After AF no change in SR content was observed (N=6, n=23). The most striking difference was observed as a reversal of the regional frequency

relationship: sparks were more frequent in non-coupled (+99±16%) vs. coupled regions in atrial myocytes from AF animals. Addition of AIP (5μM) caused a normalization in both AF and CTRL, with no change in SR content.
To further activate CaMKII, but in the absence of PKA activation, isoproterenol (100 nM) and PKI (5 μM) was added. This led to the initiation of Ca^{2+} waves in 50% of CTRL cells and 93% of AF cells.

SA278

Termination of Ca sparks: role of cytosolic and intra-luminal Ca

A.V. Zima

Department of Cell and Molecular Physiology, Loyola University Chicago, Maywood, IL, USA

The majority of Ca that initiate cardiac contraction is released from the sarcoplasmic reticulum (SR), via the process of Ca-induced Ca release (CICR)[1] mediated by ryanodine receptors (RyRs). Since CICR by definition is a self-regenerating, SR Ca release would be expected to continue until the SR Ca pool is fully exhausted. However, compelling experimental evidence shows that CICR ends when intra-SR Ca ($[Ca]_{SR}$) is only partially depleted[2-4]. Thus, a robust termination mechanism must exist to counteract the positive feedback of CICR. Despite a significant effort, the CICR termination mechanism remains unclear. This is significant because abnormal SR Ca release termination has been linked to Ca-dependent arrhythmias during cardiac pathologies such as heart failure (HF)[5].
In cardiac myocytes, SR Ca release occurs at specialized release sites that contain clusters of RyRs. Spontaneous elementary SR Ca release events, called sparks6, arise from the concerted opening of several RyRs at one release site. Sparks are measured as non-propagating local increases in cytosolic [Ca] ($[Ca]_i$). The corresponding local $[Ca]_{SR}$ depletion can be measured and is called a Ca blink[2, 4]. To explore mechanisms that control CICR termination, we simultaneously monitored local changes of $[Ca]_i$ (spark) and $[Ca]_{SR}$ (blink) in permeabilized rabbit ventricular myocytes. In addition, single cardiac RyR activity was studied after reconstruction of the channel into lipid bilayers We analyzed Ca sparks and corresponding blinks over a wide range of SR Ca loads. To decrease SR Ca load, cells were treated with the SR Ca pump inhibitor thapsigargin. Upon thapsigargin application, SR Ca load and spark frequency progressively decreased until sparks ceased when load had declined to 60% of its starting value. We also found that irrespective of SR Ca load blinks terminate at a relatively fixed level of $[Ca]_{SR}$ (60% of initial $[Ca]_{SR}$). Our data indicate that release during a spark reduces $[Ca]_{SR}$ to a critical level where RyRs in a cluster become inactive. A fall in local $[Ca]_{SR}$ may terminate a spark by two different mechanisms. First, $[Ca]_{SR}$ depletion can drive unbinding of Ca from an intra-SR RyR regulatory site and thus promote RyR closing[7,8]. Second, local $[Ca]_{SR}$ depletion can terminate a spark by reducing the unitary RyR current, decreasing $[Ca]_i$ around a cluster and thus breaking the local positive feedback of CICR[9].
The contribution of the latter mechanism to CICR termination has not been systematically explored. We studied effects of Mg and caffeine (compounds which change RyR sensitivity to $[Ca]_i$) on Ca spark termination. Cytosolic Mg (0.7 mM) decreased RyR activity by 80%, whereas caffeine (0.2 mM) increased it by 110%. We found that RyR inhibition by Mg decreased spark amplitude, width and Ca release flux. Moreover, Ca sparks terminated at 85% of the initial $[Ca]_{SR}$, much higher than for blinks observed in the absence of RyR inhibition (60%). On the other hand, RyR $[Ca]_i$ sensitization by caffeine had the opposite action on Ca spark termination. Caffeine (0.2 mM) increased Ca spark amplitude and decreased the $[Ca]_{SR}$ level at which sparks terminated (by 20%). We also explored how changes in cytosolic Ca buffering affect Ca spark termination. No substantial changes in single RyR function were observed in the presence of cytosolic BAPTA (a fast Ca buffer) if free [Ca] was kept constant. However, the same cytosolic [BAPTA] added to permeabilized myocytes significantly suppressed Ca spark activity. This BAPTA effect on sparks was not due to decrease in SR Ca load. Moreover, the fast cytosolic Ca buffer caused faster CICR termination at higher $[Ca]_{SR}$. In contrast, lowering cytosolic Ca buffering (by decreasing [EGTA]) drastically increased Ca spark frequency and width, leading to generation of multifocal (or propagating) sparks. By enhancing local CICR, a low [EGTA] solution decreased the termination $[Ca]_{SR}$ level for Ca sparks.
Finally, we studied if Ca spark termination was altered in myocytes from failing hearts, where remodeling processes lead to RyR malfunction. Recordings of RyR activity revealed that the channel sensitivity to $[Ca]_i$ is significantly increased in rabbit HF myocytes. In cells, this alteration of RyR function in HF causes termination of global Ca transients and local Ca sparks at significantly lower $[Ca]_{SR}$ compared to that in non-failing myocytes. We suggest that increased RyR sensitivity to $[Ca]_i$ allows HF myocytes to maintain systolic SR Ca release of nearly normal size even at a depleted SR Ca load. However, this RyR modification contributes to enhanced SR Ca leak and increased propensity of arrhythmogenic Ca waves.
Collectively, our results indicate that cardiac Ca sparks terminate when $[Ca]_{SR}$ fall to a certain critical level, supporting the existence of a functional link between partial $[Ca]_{SR}$ depletion and CICR termination. This functional link likely involves falling single RyR Ca flux and Ca unbinding from an intra-SR RyR Ca regulatory site as local $[Ca]_{SR}$ falls. We conclude that multiple $[Ca]_{SR}$-dependent termination mechanisms likely co-exist to ensure a stability of cardiac Ca cycling.

Slow Ca^{2+} sparks de-synchronize Ca^{2+} release in failing cardiomyocytes

W.E. Louch[1,2], J. Hake[3,4] and O.M. Sejersted[1,2]

[1]Institute for Experimental Medical Research, Oslo University Hospital Ullevål and University of Oslo, Oslo, Norway, [2]KG Jebsen Cardiac Research Center and Center for Heart Failure Research, University of Oslo, Oslo, Norway, [3]Simula Research Laboratory, Lysaker, Norway and [4]Department of Bioengineering, University of California San Diego, La Jolla, Norway

Systolic heart failure has been widely reported to involve reduced contraction magnitude of individual cardiomyocytes. However, accumulating data indicate that contraction is also slowed in this condition, which contributes to a reduced power of the heartbeat [1]. We and others have identified that a slowed rising phase of the Ca^{2+} transient is a critical underlying mechanism [1-3]. Although Ca^{2+} entry through Ca^{2+} channels is generally reported to be unaltered in failing cells, triggered release of Ca^{2+} from the sarcoplasmic reticulum (SR) via ryanodine receptors (RyRs) is de-synchronized and slowed [2,3]. This results, at least in part, from altered structure of T-tubules, which are invaginations of the surface sarcolemma. T-tubules become lost and/or disorganized during heart failure, which effectively removes some Ca^{2+} channels from their dyadic junctions with clusters of RyRs [2,3]. Thus, a significant proportion of RyRs are "orphaned" during heart failure, and Ca^{2+} release is delayed at these sites, as it is dependent on Ca^{2+} diffusion following release from intact dyads. However, we previously reported that irregular gaps between T-tubules and the formation of orphaned RyRs accounted for only a fraction of the overall slowing of the Ca^{2+} transient in this condition [2]. Thus, we presently hypothesized that alterations in RyR function also contribute to slowing of Ca^{2+} release in a mouse model of congestive heart failure (CHF) following myocardial infarction. Myocardial infarction was induced by left coronary artery ligation in anaesthetized (2.5% isoflurane inhalation) 8-10 week old C57BL/6 mice. SHAM-operated mice served as controls. Using echocardiography, animals which had developed CHF at 1 week following surgery were distinguished from non-failing animals by increased left atrial diameter (>2.0 mm) and infarct size >40% of the total left ventricular circumference. CHF was then allowed to progress until 10 weeks post-infarction when animals were sacrificed. Cardiomyocytes were isolated from viable regions of the septum. Field-stimulated Ca^{2+} transients (fluo-4 AM) rose markedly slower in CHF than SHAM myocytes as indicated by longer time to peak values (CHF=152±12% of SHAM, n_{cells} =22, 23 in SHAM, CHF, P<0.05). The rise time of Ca^{2+} sparks was also increased in CHF (SHAM=9.6±0.6 ms, CHF=13.2±0.7 ms, n_{sparks}= 89, 254 in SHAM, CHF, P<0.05), due to a sub-population of sparks (≈20%) with markedly slowed kinetics. Importantly, these slow sparks were distinct from prolonged, plateau-like Ca^{2+} release events, known to result from RyR subconductance states [4]. Regions of the cell associated with slow spontaneous sparks also exhibited slowed Ca^{2+} release during the action potential. Thus, greater variability in spark kinetics in CHF promoted less uniform Ca^{2+} release across the cell. As expected, dyssynchronous Ca^{2+} transients in CHF additionally resulted from T-tubule disorganization, as indicated by fast Fourier transforms. However, simultaneous imaging of T-tubules and Ca^{2+} indicated that slow sparks were not associated with orphaned RyRs. We instead hypothesized that an altered spatial configuration of RyRs could account for slow sparks. Western blotting revealed reduced RyR expression in CHF and, using an extended version of the sticky cluster model [5], we observed that reducing RyR density in the dyad could slow the rate of rise of the Ca^{2+} sparks. More dramatic slowing of Ca^{2+} release was modeled by distributing RyRs into sub-clusters, as there was a time delay inherent in the propagation of Ca^{2+} between sub-clusters. Adjusting other parameters in the model such as the physical coupling ("stickiness") of RyRs, junctional SR volume, cytosolic and SR [Ca^{2+}], and RyR triggering threshold did not produce slow sparks. Thus, our results suggest that altered configuration of dyadic RyRs can produce abnormally slow Ca^{2+} sparks in CHF. In combination with disrupted T-tubule structure, these alterations promote slowed, dyssynchronous Ca^{2+} transients in this condition.

A modified local control model for Ca transients in cardiomyocytes

J. Bridge

CVRTI, University of Utah, Salt Lake City, UT, USA

It is widely accepted that Ca transients in ventricular heart cells are produced by the summation of locally controlled release events. These release events are produced by couplons that reside in junctions. However we have recently shown that in isolated rabbit ventricular cells t-tubules are lost during the isolation procedure. This creates a significant number of RyR clusters that are non junctional and no longer exists as part of the couplon but are still able to release Ca (1). These non-junctional RyRs are far less numerous in tissue.. We studied mechanisms by which Ca is release is locally controlled from both couplons and non-junctional RyR clusters. Since t-tubules are known to be lost in various pathological conditions isolated rabbit cells provide a convenient model to study the nature of Ca transients in disease states. We have already established that, provided intracellular Na is present local release

events are produced with a probability approaching 100%(2). We therefore investigated a possible mechanism that could explain this. With action potential shaped voltage clamp pulses we measured a significant Na current and an accompanying Ca transient using epiflourescence (3). However if the clamp pulse was preceded by a ramp, which inactivated all Na current the Ca transient, was reduced by 27%. We next investigated trans membrane Ca flux in isolated cells in which SR release flux was blocked. There was little difference in trans membrane Ca flux with and without the Na current. We therefore conclude that Ca current carries the majority of the flux. It therefore appears that a very small Ca flux mediated by NCX can have a large effect on SR Ca release if the SR is functioning. We further investigated this with a hypothesis first proposed by Maier et al (4). That Ca release can be mediated by a brain type (TTX sensitive Na channels). We measured SR release flux in the presence of 100 nM TTX and observed a 33 % reduction in release flux (similar to that produced by elimination of all Na currents). To explain this we propose that TTX sensitive Na currents are activated upon membrane depolarization and that that this primes the junctional cleft with Na. This Na in turn causes reverse NCX, which in turn primes the junction with Ca without triggering SR Ca release. Since we expect the relationship between SR Ca release and junctional Ca concentration to be sigmoid we imagine that priming the junction causes junctional Ca to increase along the foot of this sigmoid curve. Therefore when Ca currents are activated thy act on the steep portion of this curve which increases their coupling fidelity (5). Thus we view junctional priming as a mechanism that increases the coupling fidelity of Ca currents during an action potential. This ensures a high probability of activation of couplons and at least in part can account for the fact that local release events are observed to occur at high probability during action potentials in rabbits. We next investigated Ca transients in two dimensions using a Zeiss live 5 rapid scan head. We accomplished this by labeling cell membranes with di-8 anepps and using the Ca indicator fluo 4. Two-dimensional scans can be completed in 3.64 ms. Couplons were activated early and fairly synchronously. However Ca spread to non-junctional regions in a manner that was both temporarily and spatially inhomogeneous. In an attempt to understand whether the spread of Ca was simply due to diffusion from couplons or was due to activation of non-junctional release units we compared the spread of Ca in two dimensions with a model based on a reaction diffusion equation. The results suggested that non-junctional release units within 1 micron of the membrane (including t-tubules) were activated (presumably triggered by efflux from couplons). Beyond this distance we could not determine the extent to which non-junctional release unit were activated. These inhomogeneous Ca transient are expected to produce inhomogeneous sarcomere shortening with considerable weakening of contraction. Presumably this provides at least one explanation for the failure of contraction in end stage heart disease. We suggest therefore that local control of couplons does not simply occur by activation of Ca currents within the couplon but also involves Ca priming of the junctional cleft. Non-junctional RyRs are controlled by activation of local couplons but this control is more spatially extended. Moreover we suggest that a high probability of activation of couplons ensures optimal activation of non-junctional release units.

Mechanisms of vascular ageing and calcification

C. Shanahan

King's College London, London, UK

Vascular calcification is a serious and ubiquitous clinical problem in ageing and is set to become increasingly prevalent as populations age. It is an independent risk factor for cardiovascular (CV) mortality and emerging evidence suggests that calcification is directly causal in the induction of CV events. Calcification of the vessel media is particularly prevalent in aged populations leading to vascular stiffening and a progressive rise in after-load stress, myocardial workload and changes in diastolic perfusion that predispose to ischemia, heart failure and arrhythmia. Vascular calcification is orchestrated by vascular smooth muscle cells (VSMCs), which undergo maladaptive osteo/chondrocytic differentiation and this, combined with cell death and vesiculation, act to promote mineral deposition in the vessel wall.

Vascular calcification is also prevalent in patients with premature ageing disorders such as Werner's Syndrome and Hutchison-Gilford Progeria Syndrome, which are caused by defects in the nuclear lamina protein, Lamin A. In these patients the accumulation of a defective form of unprocessed lamin A acts to drive VSMC degeneration and patients die prematurely of myocardial infarct or stroke within the second decade. Importantly, aged VSMCs also acquire nuclear lamina defects characterized by the accumulation of prelamin A, the immature, unprocessed form of lamin A. Prelamin A accumulation drives DNA damage and premature senescence in VSMCs and this occurs concomitantly with induction of osteo/chondrocytic differentiation and upregulation of the bone-associated proteins Runx2 and alkaline phosphatase. siRNA knockdown or chemical inhibition of key proteins regulating DNA damage signalling, such as ATM/ATR, can block VSMC osteo/chondrocytic differentiation and mineralization. Evidence suggests that prelamin A acts to promote DNA damage by interfering with the nuclear translocation of key DNA damage response proteins to sites of double strand breaks. However the factors that link DNA damage to osteo/chondrocytic differentiation remain unclear. One possibility is that aged/senescent VSMCs activate an inflammatory cytokine storm, called the senescence associated secretory phenotype (SASP), and release procalcific factors such as BMP2 and IL6 which drive osteo/chondrocytic differentiation. However other more direct mechanisms may also be involved.

Taken together emerging data has begun to highlight a key role for the nuclear lamina and DNA damage signalling in promoting VSMC ageing and calcification. These pathways should provide novel therapeutic targets for the amelioration of this detrimental age associated vascular pathology.

miRNA-125b and their targets in cardiovascular calcification

C. Goettsch

Center for Interdisciplinary Cardiovascular Sciences Brigham and Women's Hospital/Harvard Medical School, Boston, MA, USA

Cardiovascular calcification is a prominent feature of chronic inflammatory disorders — such as chronic kidney disease (CKD), type 2 diabetes (T2D), and atherosclerosis — that associate with significant morbidity and mortality. The concept that similar pathways control both bone remodeling and vascular calcification is widely accepted, but the precise mechanisms of calcification remain largely unknown. Micro-RNAs (miRNAs) are a large class of evolutionarily conserved, small, endogenous, non-coding RNAs serving as essential post-transcriptional modulators of gene expression that play a crucial role in normal physiology. The central role of microRNAs (miRNA) as fine-tune regulators in the cardiovascular system and bone biology has gained acceptance and has raised the possibility for novel therapeutic targets. Additionally, circulating miRNAs have been proposed as biomarkers for a wide range of cardiovascular diseases, but knowledge of miRNA biology in cardiovascular calcification is very limited. However, we recently provided the first miRNA-dependent mechanism in the progression of vascular calcification by demonstrating that miR-125b dysregulation leads to the transition of human coronary arterial smooth muscle cells (HCASMC) into osteoblast-like cells. Osteogenic transition of HCASMC was induced by osteogenic medium and led to matrix mineralization. Increased expression of miR-125b was time-dependent in HCASMC and diminished during osteogenesis. After 21 days in the osteogenic environment, miR-125b was significantly reduced (-42%) compared with HCASMC cultured in control medium. The expression of two miR-processing enzymes that are essential for SMC function, RNase III endonucleases DICER1 and DROSHA, were reduced in calcified HCASMCs. Furthermore, inhibition of endogenous miR-125b promoted alkaline phosphatase activity and matrix mineralization *in vitro*. Correspondingly, in vivo observations indicate that miR-125b is decreased in calcified aortas of apolipoprotein-deficient (Apoe) mice fed a high fat diet for 26 weeks compared to those sacrificed after 10 weeks. *In silico* and expression analyses revealed the osteoblast transcription factor SP7 (osterix) as a target of miR-125b. Our results suggest that miR-125b is involved in vascular calcification *in vitro* and *in vivo*, at least partially by targeting SP7. As cardiovascular calcification and bone remodeling share common mechanisms, we need an in-depth understanding of miRNA function and their association with the molecular pathogenesis of osteoporosis and vascular calcification. This knowledge will be critical for the developing of a more specific therapy for cardiovascular calcification that does not adversely affect physiological bone homoeostasis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Arterial calcification in chronic kidney disease (CKD): role of phosphate and phosphate transporters

C. Giachelli

Bioengineering, University of Washington, Seattle, WA, USA

Vascular calcification contributes to the high risk of cardiovascular mortality in CKD patients. Dysregulation of mineral metabolism, in particular elevated serum phosphate levels with associated abnormalities in phosphate-regulating hormones, is common in CKD patients, and is thought to drive vascular calcification. In this talk, I will review current concepts in the pathogenesis of vascular calcification in CKD, and highlight our recent experimental findings directed at understanding the mechanisms by which elevated phosphate promotes vascular calcification. The effects of elevated phosphate on vascular cell differentiation, apoptosis, and matrix degradation will be reviewed. We have identified sodium-dependent phosphate cotransporters as important mediators of vascular smooth muscle cell calcification in response to elevated phosphate, and data on their roles in these processes, including phosphate uptake-dependent and –independent pathways, will be presented. Unravelling the complex pathways involved in vascular calcification will ultimately provide novel targets and therapies to limit the deleterious effects of vascular calcification in CKD patients.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Calcium phosphate crystals and cell death

D. Proudfoot[1], Y. Dautova[1], D. Kozlova[2], M. Epple[2], J.N. Skepper[3] and M.D. Bootman[1,4]

[1]Signalling, Babraham Institute, Cambridge, Cambridgeshire, UK, [2]Inorganic Chemistry, University of Duisburg-Essen, Essen, Germany, [3]Department of Physiology, Development and Neuroscience, Universtiy of Cambridge, Cambridge, Cambridgeshire, UK and [4]Life, Health and Chemical Science, Open University, Milton Keynes, UK

Calcium phosphate (CaP) crystals are a natural component of bone, but are also commonly found in other tissues in association with ageing and several diseases including atherosclerosis, medial calcification (Mönckeberg's sclerosis), arthritis and cancer. The amount of CaP crystals deposited in arteries correlates positively with atherosclerotic plaque rupture and myocardial infarction but whether the crystals actively participate in driving the disease is unclear. The damaging effect of nano- and microparticulate CaP crystals in arthritic joints has been known for some time, and small CaP crystals occur in regions of atherosclerotic plaque stress and rupture. Since vascular smooth muscle cells (VSMCs) have a protective role

in plaque rupture, we investigated whether CaP crystals could affect VSMC function.
Adding either synthetic CaP crystals or calcified particles extracted from human atherosclerotic plaques to human aortic VSMCs in culture induced cell death, with the synthetic crystals being more potent than the plaque-extracted crystals. To investigate the mechanism of cell death, intracellular calcium ion levels were measured using video imaging of Fura-2-loaded cells. CaP crystals caused rapid rises in intracellular calcium ion concentration preceding cell death. Both effects were inhibited when lysosomal acidification was blocked with bafilomycin A, implicating lysosomal involvement in calcium signalling and cell death.
Video imaging of VSMCs indicated that CaP crystals induce the formation of large plasma membrane blebs prior to cell death, suggesting focal sites of plasma membrane damage. Transmission electron microscopy revealed that CaP crystals adhered to the plasma membrane within 5 minutes of addition of crystals, with crystals individually aligning with the membrane or grouped in clusters at sites of profound plasma membrane fragmentation. VSMCs did not die until approximately 30 minutes after addition of CaP crystals (measured using propidium iodide uptake), which implies that the initial plasma membrane damage does not kill cells, but rather that cells make an attempt to repair/extrude damaged components. However, continued exposure to crystals overwhelms repair and calcium homeostatic mechanisms resulting in cell necrosis.
Further studies suggest that CaP-binding proteins such as fetuin and albumin, that are known to bind to CaP crystals *in vivo*, may dampen the toxic effects of CaP on VSMCs. The coating of plaque-derived CaP crystals by these proteins could explain why they are less potent than synthetic CaP crystals in causing VSMC death. Uncovering how CaP crystals bind to VSMCs, induce damage, activate repair mechanisms, induce calcium signalling and involve key cellular organelles to result in necrosis may provide strategies to limit their damaging effects in the vessel wall.

Pro-inflammatory aspects of cardiovascular calcification: insights from molecular imaging

E. Aikawa

Cardiovascular Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

The collective global impact of the spectrum calcific cardiovascular diseases is serious but underappreciated health problem in the developed and rapidly developing regions of the world. Cardiovascular calcification is an independent risk factor for cardiovascular morbidity and mortality. Ectopic mineralization mainly affects the aorta, coronary arteries, peripheral arteries, and aortic valves, with fully-formed bone observed in atherosclerotic plaques and stenotic aortic valves. This disease of dysregulated metabolism is no longer viewed as a passive degenerative disorder, but instead as an active process triggered by pro-inflammatory cues. Hypercholesterolemia, metabolic syndrome, end-stage renal disease, diabetes mellitus and increased age accelerate cardiovascular calcification.
Traditional imaging modalities such as computed tomography, although perfectly adept at identifying and quantifying advanced calcification, cannot detect the early stages of this disorder and offer limited insight into the mechanisms of mineral dysregulation. Here we present optical molecular imaging as a promising tool that simultaneously detects pathobiological processes associated with inflammation and early stages of calcification *in vivo* at the (sub)cellular levels.
Research into treatment of cardiovascular calcification is lacking, as shown by clinical trials that have failed to demonstrate the reduction of calcific aortic stenosis. Hence the need to elucidate the pathways that contribute to cardiovascular calcification and to develop new therapeutic strategies to prevent or reverse calcification has driven our investigations.
We previously showed that early calcification/microcalcification associates with macrophage accumulation in vulnerable atherosclerotic plaques. Chronic renal disease (CRD) and mineral imbalance accelerates calcification and the subsequent release of matrix vesicles (MVs) — precursors of microcalcification. We tested the hypothesis that macrophage-derived MVs contribute directly to microcalcifications, which in turn may contribute to plaque rupture.
We showed that macrophages associated with regions of calcified vesicular structures in human carotid plaque samples (n=136 patients). *In vitro*, macrophages released MVs with high calcification and aggregation potential. MVs expressed exosomal markers (CD9 and TSG101), and contained S100A9 and annexin V (Anx5). Silencing S100A9 *in vitro* and genetic deficiency in S100A9$^{-/-}$ mice reduced MV calcification, while stimulation with S100A9 increased calcification potential. Externalization of phosphatidylserine (PS) after Ca/P stimulation, and interaction of S100A9 and Anx5, indicated that a PS–Anx5–S100A9 membrane complex facilitates hydroxyapatite nucleation within the macrophage-derived MV membrane. These results supported the novel concept that macrophages release calcifying MVs, enriched in S100A9 and Anx5, which contribute to accelerated formation of microcalcification in CRD.
This presentation will discuss studies that have used molecular imaging methods to advance knowledge of cardiovascular calcification, focusing in particular on the inflammation-dependent mechanisms of arterial and aortic valve calcification.

Deciphering dead-end docking of large dense core vesicles in chromaffin cells

S. Hugo[1], E. Dembla[1], M. Halimani[1], U. Matti[2], J. Rettig[1] and U. Becherer[1]

[1]Institut für Physiologie, Universität des Saarlandes, Homburg, Germany and [2]CBB - Ries Group, European Molecular Biology Laboratory, Heidelberg, Germany

Calcium-dependent exocytosis of large dense core vesicles (LDCVs) comprises several steps: docking of the vesicles to the plasma membrane (PM), priming to render the vesicles release-competent and fusion with the PM. Total internal reflection fluorescence microscopy (TIRFM) enables the real-time visualization of LDCVs near the PM as they undergo changes from

one functional state to the other (Nofal et al., 2007). We used this technique in combination with patch-clamp electrophysiology to study the secretion of LDCVs in bovine chromaffin cells (Becherer et al., 2007) stimulation of the cells for 5 minutes with 6 μM [Ca2+]i induced maximal secretion and a large reduction of the LDCVs density at the plasma membrane. However, 14.1 ± 1.5% of the LDCVs were visible at the plasma membrane throughout experiments, indicating they were permanently docked. We defined these vesicles as dead end vesicles. Overexpression of Munc18 2 or SNAP-25 reduced the pool size of these vesicles. Conversely, expressing open-Syntaxin increased this pool. These results indicate that the unproductive target Soluble NSF Attachment Protein Receptor acceptor complex composed of 2:1 syntaxin–SNAP-25 exists in vivo. More importantly, they define a novel function for this acceptor complex in mediating dead end docking.

DOC2B and Munc13-1 differentially regulate neuronal network activity

A. Lavi, A. Sheinin, R. Shapira, D. Zelmanoff and U. Ashery

Neurobiology, Tel Aviv University, Tel Aviv, Israel

Alterations in the levels of synaptic proteins affect synaptic transmission and synaptic plasticity. However, the precise effects on neuronal network activity are still enigmatic. Here, we utilized microelectrode array (MEA) to elucidate how manipulation of the presynaptic release process affects the activity of neuronal networks. By combining pharmacological tools and the genetic manipulation of synaptic proteins we show that overexpression of DOC2B and Munc13-1, proteins known to promote vesicular maturation and release, elicits opposite effects on the activity of the neuronal network. Although both cause an increase in the overall number of spikes, the distribution of spikes is different. While DOC2B enhances, Munc13-1 reduces the firing rate within bursts of spikes throughout the network; however, Munc13-1 increases the rate of network bursts. DOC2B's effects were mimicked by Strontium that elevates asynchronous release but not by a DOC2B mutant that enhances spontaneous release rate. This suggests for the first time that increased asynchronous release on the single-neuron level promotes bursting activity in the network level. This innovative study demonstrates the complementary role of the network level in explaining the physiological relevance of the cellular activity of presynaptic proteins and the transformation of synaptic release manipulation from the neuron to the network level.

Activity-mediate expansion of the secretory fusion pore is regulated by a calcineurin-dependent dynamin-syndapin signaling pathway in neuroendocrine mouse adrenal chromaffin cells

C. Smith and P. Samasilp

Physiology and Biophysics, Case Western Reserve University, Cleveland, OH, USA

Neuroendocrine chromaffin cells release a variety of transmitter molecules into the circulation as a specific function of sympathetic activation. Activity-dependent release of transmitter single species or classes of transmitters is controlled through regulation of the secretory fusion pore. Under sympathetic tone, basal synaptic activity drives chromaffin cells to secrete modest levels of catecholamine through a restricted secretory fusion pore. In contrast, elevated sympathetic firing, as evoked by environmental stress or injury, results in the expansion of the fusion pore for maximal catecholamine release. Pore expansion also facilitates release of co-packaged peptide transmitters from the dense granule core. Therefore, fusion pore expansion is a regulatory step for the activation of the sympatho-adrenal stress response. Despite the physiological impact and importance of this process, the molecular mechanism by which pore expansion is regulated remains unresolved. Here we employ fluorescence imaging in combination with electrophysiological and electrochemical-based measurements to test the role of dynamin I in the regulation of activity-mediated fusion pore expansion in mouse adrenal chromaffin cells (Samasilp et al., 2012). We show that under elevated electrical stimulation, dynamin I is dephosphorylated at Ser-774 by the protein phosphatase, calcineurin. We also demonstrate that disruption of dynamin I binding to syndapin, a step regulated by calcineurin-dependent dynamin dephosphorylation, inhibits fusion pore expansion. Lastly, we show that pharmacologic block of N-WASP function (a syndapin binding partner) limits activity-dependent expansion of the fusion pore. Our results suggest that fusion pore expansion is regulated by a calcineurin-dependent dephosphorylation of dynamin I. Dephosphorylated dynamin I acts via a syndapin/N-WASP signaling cascade, leading to pore expansion.

Studies of a cyclic nucleotide regulated potassium channel

J. Morais Cabral

IBMC, Porto, Portugal

The superfamily of cyclic nucleotide regulated cation channels includes the eukaryotic hyperpolarization-activated cyclic nucleotide-gated (HCN) and cyclic nucleotide gated (CNG)

channels as well as a family of bacterial cyclic nucleotide regulated potassium channels. All of these channels are tetramers, with each subunit having 6 trans-membrane helices and a C-terminal cytosolic cyclic nucleotide binding (CNB) domain. The major difference between the eukaryotic and bacterial channels is the presence, in the eukaryotic membrane proteins, of a long linker (the C-linker) between the channel regions and the CNB domain. Despite this major difference, structural studies of the MlotiK1 bacterial channel (1,2,3) have provided general insights into the ligand-dependent conformational changes occurring in the CNB domains and about the structural properties of cation channels with 6 trans-membrane helices, such as voltage-gated potassium channels. This bacterial channel also displays specific properties that are very different from the properties of the eukaryotic channels (4). Interestingly, the recently determined structures of CNB-like domains from eukaryotic EAG channels have raised the possibility of novel molecular mechanisms of regulation by domains with this fold (5,6).

Structure and regulation of the CorA magnesium channel

J. Payandeh

Structural Biology, Genentech, Inc., South San Francisco, CA, USA

The magnesium ion (Mg^{2+}) is the most abundant intracellular divalent cation and plays an essential role in a myriad of biochemical processes. Proper Mg^{2+} homeostasis has been correlated with physiological well-being and Mg^{2+} deficiency is associated with pathological states including cardiac syndromes, immunodeficiency, epilepsy, migraine, muscular dysfunction and bone wasting. Despite its impact on human health, relatively little is known about the molecular mechanisms that regulate Mg^{2+} transport and storage. I will describe a series of recent crystal structures of the CorA Mg^{2+} channel from *Thermotoga maritima* that have provided the first structural insights into the gating and selectivity mechanisms operating in this unique channel superfamily. CorA is revealed to be a funnel-shaped homopentamer containing a large intracellular regulatory domain linked through an extended alpha-helix to a membrane-embedded ion pore. Functional analysis and molecular dynamics simulations confirm that CorA contains an intrinsic and elaborate Mg^{2+}-sensor which couples cellular Mg^{2+} status to the regulation of its ion pore. The CorA pore appears to be sealed by at least two gates in its closed state, which suggests that cellular Mg^{2+} transport is well guarded and very tightly regulated.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Activation and inhibition of prokaryotic pentameric ligand-gated ion channels

R. Dutzler

Dept. of Biochemistry, University of Zurich, Zurich, Switzerland

The pentameric ligand-gated ion channels (pLGICs) are ionotropic neurotransmitter receptors that mediate electrical signaling at chemical synapses. The X-ray structures of two prokaryotic homologues have provided first insight into the detailed architecture of the family at high resolution [1]. The structure of GLIC, a proton-activated channel from the cyanobacterium Gloebacter violaceous shows an open conformation of the pore [2]. The channel conducts cations with similar properties as the nicotinic acetylcholine receptor (nAChR). The transmembrane pore is funnel-shaped with a wide hydrophobic entrance at the extracellular side that narrows to a hydrophilic intracellular opening. In this region conserved residues coordinate ions which have lost a large part of their hydration shell [3]. The structure of ELIC, a pLGIC from the plant pathogen Erwinia chrysanthemi, shows a non-conducting conformation that was obtained in the absence of ligands [4]. In its structure the extracellular half of the pore is occluded by bulky hydrophobic residues that likely prevent ion conduction. ELIC is activated by a set of primary amines that include the neurotransmitter GABA [5]. The protein forms cation selective channels with large conductance that slowly desensitize in the presence of ligands. Both proteins were used to study distinct mechanisms of channel inhibition. Ion conduction in GLIC is inhibited by the same set of open channel blockers that also act on nAchRs [3]. In ELIC acetylcholine acts as competitive inhibitor, which binds to the agonist site and stabilizes the closed conformation of the channel. Divalent cations, in contrast, are allosteric modulators, which bind to a site distant from the agonist binding site where they interfere with gating [6]. The strong structural similarity to their eukaryotic counterparts make ELIC and GLIC important model systems for the pLGIC family that will ultimately allow a detailed comprehension of mechanistic properties that are still poorly understood.

Comparison of the structure of a potassium channel in both 2D and 3D crystals

R. De Zorzi[2], L. Bannwarth[1], W. Nicholson[2] and C. Venien-Bryan[1,2]

[1]IMPMC, UMR 7590, CNRS-UPMC-IRD, UPMC, Paris6, Paris, France and [2]Biochemistry, University of Oxford, Oxford, UK

Inwardly-rectifying potassium (Kir) channels regulate membrane electrical excitability and K+ transport in many cell types where they control such diverse processes as heart rate, vascular tone, insulin secretion and salt/fluid balance. Their physiological importance is highlighted by the fact that genetically inherited defects in Kir channels are responsible for a wide-range of channelopathies. To elucidate how channel function becomes defective in the disease state requires a detailed understanding of channel structure in both the open and closed states. Here for the first time, we report the structure of a KirBac potassium channel with an open bundle crossing indicating a mechanism of channel gating determined by X-ray crystallography at 3Å resolution. In this model, the rotational twist of the cytoplasmic domain is coupled to opening of the bundle-crossing gate via a network of inter- and intra-subunit interactions [1]. In addition, we have also used EM analysis of 2D crystals of the same Kir channel trapped in an open state and compared these results with the 3D structure.

Intriguingly, the projection maps from the EM experiments suggest a larger opening of the pore in the 2D crystal form compared to that observed in the 3D crystal structure [2]. The organization of these two crystal forms is different and suggests that the 2D crystals may permit stabilisation of an open state structure that is not compatible with 3D crystallisation. These results not only have major implications for our understanding of the open state structure of the Kir channel, but more importantly they demonstrate the general utility and importance of methods such as electron microscopy and 2D crystallography for the study of membrane protein structure.

Biomechanical control of the SMC phenotype during arteriogenesis

T. Korff

Institute of Physiology and Pathophysiology, Heidelberg University, Heidelberg, Germany

Arteriogenesis is an important adaptive remodeling process which involves the enlargement and thickening of arterioles running in parallel to an occluded artery, and is capable of partially compensating the consequences of peripheral artery disease by creating natural bypasses. The arteriolar remodeling is orchestrated by changes in the biomechanical forces to which the vessel wall is exposed to. Based on Poiseuille's equation, progressive stenosis of the main artery will lead to an increase in resistance hence to a significant drop in pressure distal to the site of occlusion. As a consequence, the pressure difference between both ends of the collateral arterioles is enhanced resulting in an increased flow and, as a consequence, an increase in shear stress.

Laminar shear stress is thought to be responsible for the initial dilation of the collateral arterioles through activation of endothelial cell nitric oxide synthase. Moreover, the NO-mediated dilation decreases the wall thickness and thus - according to the Laplace equation - results in an increase in circumferential wall stress. While the impact of shear stress on collateral growth has been extensively studied, the role of circumferential wall stress in the early phase of arteriogenesis is less well defined. To this end, our studies indicate that wall stress or biomechanical stretch activates the transcription factor AP-1 in endothelial and smooth muscle cells and controls the expression of MCP-1 - an important determinant of arteriogenesis. Furthermore, this biomechnical force promotes the activation of smooth muscle cells by imparing the function of myocardin - a crucial regulator of the contractile capacity of these cells - and acts in concert with shear stress to reprogram G-protein signaling cascades in smooth muscle cells.

Collectively, our findings suggest that biomechanical stress controls rate-limiting mechanisms during the remodeling of

collateral arterioles and contributes to a mechanosensitive gene expression in vascular smooth muscle cells during arteriogenesis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Inhibition of individual 14q32 microRNAs drastically increases neovascularization and blood flow recovery after ischemia

S.M. Welten[1,2], A.J. Bastiaansen[1,2], A.A. Hellingman[1], R.C. de Jong, M.R. de Vries, H.A. Peters, E.R. Kandimalla, P.H. Quax and A.Y. Nossent[1]

[1]Department of Vascular Surgery, Leiden University Medical Center, Leiden, Netherlands, [2]Einthoven Laboratory for Experimental Vascular Medicine, Leiden University Medical Center, Leiden, Netherlands and [3]Idera Pharmaceuticals, Cambridge, MA, USA

Background. Neovascularization, i.e. angiogenesis and arteriogenesis is a multifactorial process. As microRNAs can regulate expression of up to several hundred target genes, we set out to identify microRNAs that target genes in all pathways of neovascularization. Using www.targetscan.org, we performed a reverse target prediction on a set of 197 genes involved in neovascularization. We found enrichment of binding sites for 27 miRs in a single microRNA gene cluster. MicroArray analyses showed that 14q32 microRNAs were down-regulated during neovascularization in mice subjected to single femoral artery ligation.
Methods and Results. Novel microRNA-inhibitors, Gene Silencing Oligonucleotides (GSOs), were used to inhibit four 14q32 microRNAs, miR-487b, miR-494, miR-329 and miR-495 one day prior to double femoral artery ligation. Blood flow recovery was followed by Laser Doppler Perfusion Imaging. All 4 GSOs clearly improved blood flow recovery after ischemia. Mice treated with GSO-495 or GSO-329 showed increased perfusion already after 3 days (30% perfusion vs. 15% in control) and those treated with GSO-329 showed a remarkable full recovery of perfusion after 7 days (vs. 60% in control). Increased collateral artery diameters (arteriogenesis) were observed in adductor muscles of GSO-treated mice, as well as increased capillary densities (angiogenesis) in the ischemic soleus muscle. In vitro, treatment with GSO-329, GSO-495 and GSO-487 led to increased arterial endothelial cell activation whereas treatment with GSO-494 led to increased arterial fibroblast proliferation.
Conclusions. Inhibition of 14q32 miRs leads to drastic increases in post-ischemic blood flow recovery in vivo and may offer an alternative to growth factors in therapeutic neovascularization.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Vasomotor properties of collateral arteries: effects of exercise training

M.H. Laughlin

Biomedical Sciences, University of Missouri, Columbia,, MO, USA

The purpose of this paper is to characterize the vasomotor properties of collateral vessels and summarize knowledge of the impact of exercise training/physical activity (EX) on these properties. The focus is on vasomotor properties of collateral vessels that provide blood flow to cardiac and skeletal muscle because this is my experience.
Vasomotor Properties of Collaterals: In response to occlusive vascular disease inadequate blood flow is provided downstream of the occlusion which chronically stimulates a number of adaptations that help restore blood flow toward normal. Structural enlargement of collateral vessels is well characterized in animal models (Laughlin et al. 2012). There is relatively less appreciation of the importance of vasomotor reactivity of collateral vessels but it is known that vasomotor properties of collateral arteries differ from those of normal arteries. Compared to normal arteries, the constrictor response to ET-1, U46619, KCl, thromboxane A2, are reported to be blunted in collateral arteries (Angus et al.1991). Dilator responses to adenosine SNP and cromakalin are normal or increased in collaterals. In contrast, endothelium-dependent dilation (EDD) is generally reported to be blunted in peripheral collateral arteries (Taylor et al. 2008) and collateral dependent coronary arteries and arterioles (Griffin et al. 1999 & 2001). Peripheral collateral arteries exhibit unaltered constrictor responses to phenylephrine (Taylor et al. 2008).
It is possible that these EDD is blunted due to decreased intravascular pressure downstream of arterial occlusion (EDD is blunted when normal arteries are evaluated at the low pressures comparable to those reported in collateral vessels.) On the other hand, the low luminal pressure caused by upstream obstruction also modifies flow distribution to enhance blood flow through the collateral circuit in a nitric oxide (NO)-dependent manner. When exercise is imposed on the collateral circuit, it may result in an increased shear stress and thereby contribute to the enlargement of, and increased EDD of, the collateral vessels.
Flow-induced dilation, an EDD response, is blunted in collateral arteries. Indeed, peripheral collateral arteries exhibit a modest dilation at low shear stress and then a significant vasoconstriction with increasing shear stress whereas similarly sized arteries simply demonstrate dilation. Colleran et al (2010) suggested this may be the result of an interaction of NO with reactive oxygen species (ROS) producing peroxynitrite which stimulates vasoconstriction via thromboxane A2 production through the COX pathway.
Effects of exercise training: Several investigators have tested the hypothesis that, since shear stress is increased during exercise (due to the increased blood flow), chronic EX would stimulate adaptations in vasomotor control of collateral vessels including an enhanced EDD (Laughlin et al. 2012). In addition, it appears that EX can modify the responses of vascular smooth muscle in collateral arteries as evidenced by an EX-induced reversal of the modest reduction in vasodilator responsiveness to sodium nitroprusside (Colleran et al. 2010). Colleran et al also reported that EDD responses were significantly greater to both ACh and intravascular flow in collateral arteries of EX rats. Neither blockade of COX with indomethacin nor block-

ade of endothelial nitric oxide synthase with NG-nitro-L-arginine methyl ester eliminated the increased EDDs.
The coronary literature does not consistently indicate enhanced growth of collateral arteries in models of coronary artery disease (CAD) or in patients with CAD after EX. However, it appears that EX has beneficial effects on the vasomotor reactivity of collateral arteries and/or vasomotor control of resistance in collateral-dependent myocardium. For example, it is reported that collateral-dependent coronary arteries exhibited improved EDD and improved adenosine-induced vasodilation in EX animals. EX also improved bradykinin-induced EDD in arterioles from collateral-dependent myocardium and VEGF165-induced EDD was reported to be enhanced in collateral-dependent arterioles. Fogarty et al. (2004) also reported that the enhanced VEGF-induced EDD was mediated principally via increased NO bioavailability.
EX appears to increase myogenic tone in arterioles isolated from collateral-dependent zones of models of CAD in a manner similar to that reported for arterioles from normal EX hearts (Laughlin et al. 2012). EX is also reported to enhance endothelin-1-mediated contractile responses in collateral-dependent resistance arteries and to exhibit increased basal tone, and increased K+ channel activity (Laughlin et al. 2010).

Constraint-based analysis of energy metabolism in mitochondrial diseases

E. Marchiori and W. Megchelenbrink

Radboud University, Nijmegen, Netherlands

Genome-scale metabolic networks can be reconstructed using a constraint-based modeling approach. The stoichiometry of the network and the physiochemical laws still enable organisms to achieve certain objectives -such as biomass composition- through many various pathways. This means that the system is under-determined and many alternative solutions exist. A recent popular method used to reduce the number of alternative pathways is Flux Balance Analysis (FBA), which tries to optimize a given biological objective function. FBA does not always find a correct solution and for many networks the biological objective function is simply unknown. As a consequence researchers may have to measure certain fluxes. In this talk we discuss a method that combines a sampling approach with a greedy algorithm for finding a small given number of fluxes that, if measured, are expected to reduce as much as possible the solution space towards the true flux distribution. The method can be used for guiding the biologists to perform experimental analysis of metabolic networks. We will also shortly review studies that focus on constraint-based models of normal and malfunctioning mitochondria.

Detecting gene-gene interactions in genome-wide association studies of complex diseases

H.J. Cordell

Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, UK

Over the last 5 to 6 years, genome-wide association studies (GWAS) have proved enormously successful for the detection of genomic regions that harbour genes associated with complex diseases and quantitative traits. However, moving from a replicable association signal to determination of the underlying causal genetic variant and an understanding of its mechanism has proved more challenging. The variants detected in GWAS generally confer modest effects (odds ratios of 1.5 or less), making them of limited use for risk prediction, and do not generally account for a large proportion of the observed heritability (the additive genetic contribution to the overall trait variance), suggesting there are many additional, possibly interacting, genetic contributors to be found. From a biological perspective, interactions between genes (epistasis) are expected to be ubiquitous, as complex biological phenotypes are likely to result from complex combinations of genetic (and non-genetic) factors rather than from such factors operating in isolation. In this talk I will discuss the statistical challenges involved in, and some possible strategies for, detecting and modelling gene-gene interactions using GWAS data. I will focus on some recent work carried out by ourselves and others to develop tests that show high power over a wide range of scenarios while maintaining an acceptable false positive rate.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Molecular programming of cell and vessel phenotypes during neurovascular formation

D. Ryan, B. Long, R. Rekhi, A. Abrego, B. Zaunbrecher, A. Mahadevan and A.A. Qutub

Bioengineering, Rice University, Houston, TX, USA

Brain hypoxia affects hundreds of thousands of people annually, leading to perinatal brain injury, complications of ischemic

strokes, vascular dementia, and neurodegeneration. Despite this, there are no FDA approved drugs specifically targeting brain hypoxia. Regeneration of capillaries, or therapeutic angiogenesis, is a strategy to treat patients with brain hypoxia. One way to accomplish this is by enhancing or mimicking the body's own angiogenic response. A challenge lies in understanding this response with the mechanistic-detail needed to develop effective therapeutic strategies.
Methods: Two main growth factors that regulate angiogenic sprouting in the brain are vascular endothelial growth factor (VEGF) and brain-derived growth factor (BDNF). We present an integrated computational-experimental strategy to characterize human endothelial cell-cell interactions as a function of these proteins. We introduce a 3D "rules-as-agents" model of cell movement that allows rapid testing and comparison of multiple hypotheses to in vitro angiogenesis experiments. Endothelial cells are represented as machines that transition between finite behavior states, and their properties are explored by a genetic search algorithm. We rank and quantify differences between competing hypotheses about cell behavior during the formation of unique capillary phenotypes. We validated the 'state-machine' paradigm through in vitro assays. In vitro assays included 3D angiogenic spheroid assays and the 2D classification of primary human umbilical vein endothelial cell (HUVEC) states as a function of varying concentrations and combinations of BDNF and VEGF (control; 25 ng/ml VEGF; 50 ng/ml VEGF; 25 ng/ml VEGF, 25 ng/ml BDNF; 25 ng/ml VEGF, 50 ng/ml BDNF; 50 ng/ml VEGF, 100 ng/ml BDNF; 50 ng/ml BDNF; 100 ng/ml BDNF), at 6, 12, 24 and 48 hrs of stimulation. Hierarchical and k-means cluster analysis coupled to molecular imaging identified similarities between stimulated HUVEC based on 7 main categories including intracellular cytoskeletal regulation, actin fiber alignment, and network connectivity.
Results: Our best adaptive state machine models of endothelial cell behavior as a function of BDNF and VEGF predicted novel in vitro results within a standard deviation of all measurements (22% of models). Cluster analysis of >10,000 endothelial cells revealed a set of dominant morphological phenotypes and cell-cell connectivity. These results show that VEGF and BNDF can reproducibly induce unique frequencies of behavior; morphological angiogenic states; and cell-cell connectivity in 2D and 3D. Ongoing work involves delineating the effect of these identified endothelial cell phenotypes and networks on neural function. This work offers the ability to understand – and ultimately control – human cell behavior at the microvasculature level. Applications of these technologies include guiding regenerative therapies targeting the neurovasculature.

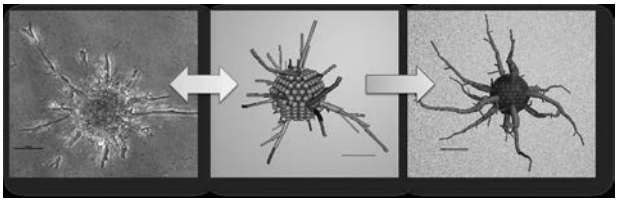

Figure 1. From in vitro observations, a framework for controlling endothelial cell behavior c(x,t) as a function of BDNF and VEGF can be created to produce a specific capillary phenotype p(x,t).

Remembrances of things past, and the epigentic origins of phenotypic variation and disease risk

J.H. Nadeau

Pacific Northwest Research Institute, Seattle, WA, USA

Both humans and animal models provide many examples of highly heritable traits where the disease-causing genetic variants elude discovery. In these cases, heritability is often high but the explained genetic variance is low. The usual explanation involves undetected genetic variants with weak and heterogeneous actions in affected individuals. This explanation is reasonable given the limited statistical power in most genetic studies. However, we recently found several examples of heritable epigenetic changes, through the germline, suggesting that modes of inheritance other than DNA can also be transmitted across generations to affect phenotypic variation and disease risk. In each case, genetic variants in ancestral generations lead to phenotypic variation in subsequent generations. These effects can be as common and strong as those resulting from conventional inheritance, and they can persist for multiple generations. Transgenerational inheritance affects cancer, metabolic diseases, behaviors and many other traits. The effects are usually specific to one germ-lineage, with examples of transmission through the female germ-lineage and others through the paternal germ-lineage. The identity of the genes that mediate these effects implicate aspects of RNA biology including RNA editing, demethylation, translation control, and regulation of miRNA biology. These transgenerational effects challenge our understanding of inheritance and the origins of phenotypic variation and disease risk.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Sphingolipid-induced nutrient transporter loss as a mechanism for growth control

A. Edinger

Developmental and Cell Biology, University of California Irvine, Irvine, CA, USA

All rapidly growing cells must take up extracellular nutrients at an accelerated rate to support the anabolism required to double cell mass. Restricting nutrient access will thus limit cell proliferation. Moreover, because the mutations that occur in cancer cells make them metabolically inflexible, nutrient deprivation will be more detrimental to transformed than non-transformed cells. When nutrient limited, normal cells become quiescent and catabolic, entering a hibernation-like state. Cancer cells, in contrast, cannot respond adaptively to starvation and continue to try to grow, forcing themselves into a bioenergetic crisis. As a result of these differences in metabolic wiring, a therapeutic compound that triggers nutrient transporter loss would likely be an effective and selective cancer therapy. Sphingolipids have an evolutionarily conserved role as regulators of nutrient transporter surface expression. In heat stressed stressed yeast, sphingolipids cause nutrient permease down-modulation that protects cells by slowing growth. We found that ceramide and the sphingosine-like drug FTY720 trigger the rapid down-regulation of nutrient transporter proteins in a variety of mammalian cell types. Restricting nutrient access in this way is indeed more toxic to cancer cells than to normal cells. To better understand which oncogenic mutations confer sensitivity and resistance to sphingolipid-induced nutrient transporter loss, we compared the sensitivity of TSC2 wildtype and knockout fibroblasts to ceramide. TSC2-/- cells have constitutively high mTORC1 activity. The mTORC1 kinase complex is active in most cancer cells where it drives protein translation, glycolysis, and lipid synthesis. TSC2 is a critical negative regulator of mTORC1 under unfavorable growth conditions. Because they cannot reduce anabolism, TSC2-/- cells are hypersensitive to glucose withdrawal. Surprisingly, we found that TSC2-/- cells were resistant to death induced by sphingolipids. Although amino acid and glucose transporters were initially down-regulated, TSC2-/- cells mounted an exaggerated adaptive response to nutrient stress exhibiting a dramatic, mTORC1-dependent up-regulation of new transporter proteins. Patients heterozygous for inactivating mutations in TSC1 or TSC2 develop benign hamartomatous growths and we propose that this loss of tissue homeostasis might be due in part to the ability of TSC1/2 deficient cells to overcome nutrient or ceramide enforced limits on growth. Interestingly, these hamartomas do not progress to malignant disease. Consistent with this, we found that introducing the potently transforming H-RasV12 mutant reversed the survival advantage of TSC2-/- MEFs, apparently by increasing nutrient demand. These results support the idea that fully transformed cancer cells will be susceptible to drugs targeting transporter proteins. Along these lines, we are developing new analogs of FTY720. FTY720 is effective in multiple animal models of cancer, but cannot be used in human patients because it causes profound bradycardia by affecting sphingosine-1-phosphate receptors 1 and 3. We have found that FTY720's effects on S1P receptors and nutrient transporter proteins are separable and unrelated. FTY720 analogs designed to lack S1P activity are effective anticancer agents both in vitro and in vivo. Moreover, these compounds show striking synergy with other compounds targeting the metabolic changes associated with cancer including mTORC1 activation. Together, these studies suggest that these novel compounds targeting multiple nutrient transporters simultaneously could prove to be safe and effective anti-cancer therapies.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Cellular nutrient sensing in cancer

D.C. Goberdhan

Physiology, Anatomy and Genetics, University of Oxford, Oxford, Oxon, UK

The fundamental cellular roles of mechanistic (formerly mammalian) Target of Rapamycin Complex 1 (mTORC1) activity are evident from the wide range of major human diseases in which it is misregulated, including the majority of human cancers, neurodegenerative disorders, cardiovascular disease, diabetes, obesity and other age-related disorders. mTORC1 is a key signalling hub that controls cellular homeostasis by responding to a diverse range of physiological inputs, like endocrine insulin/insulin-like growth factors (IGFs), energy levels (ATP:AMP ratio), oxygen levels, and local amino acid (AAs) to modulate cellular metabolism and growth (reviewed in Malik et al., 2012 [epub]). There are, however, still significant gaps in our understanding of local AA regulation of mTORC1, which takes place at the surface of late endosomes and lysosomes (LELs; reviewed in Durán and Hall 2012). Intracellular AAs have been highlighted as playing a key role in activating mTORC1, via two very different, but not necessarily mutually exclusive mechanisms. The first involves sensing of cytosolic leucine and the second the sensing of AA within late endosomes and lysososomes (LELs).

Charged Leucyl tRNA Synthetase (LRS) seems to act as a direct sensor of cytosolic leucine levels, leading to interaction with the Rag GTPases on LELs and subsequent activation of mTORC1. However, the proposed mechanism differs significantly between human cells and yeast, and a key residue involved in the human mechanism is not conserved in fly LRS (reviewed in Durán and Hall 2012).

Unbiased screening in flies and subsequent analysis in human cells led us to identify the Proton-assisted Amino acid Transporter (PAT/SLC36) family located at the surface of LELs, as central players in AA-dependent mTORC1 activation (Heublein et al., 2010; Ögmundsdóttir et al., 2012). Our studies have focused on the two ubiquitous human PAT transporters, PAT1 and PAT4. While modest overexpression of PAT1 leads to mTORC1 activation and increased cell growth and proliferation (Ögmundsdóttir et al., 2012, higher levels reduce tissue growth and mTORC1 signalling (Goberdhan et al., 2005; Zoncu et al., 2011), most likely due to a dominant negative effect. The discovery that LEL-located PAT1 interacts with Rags and is required to activate mTORC1 and promotes cell proliferation, together with a substantial amount of work from the Sabatini lab, has highlighted a multi-protein complex that we have called the 'nutrisome', located on the LEL surface. The nutrisome appears to respond to the intraluminal pool of AA within LELs, reflects LEL extracellular AA levels (for details see Figure 1; reviewed in Malik et al., 2012 [epub]).

Aggressive tumour cells are able to survive and grow even when poorly vascularised with limited access to growth factors and nutrients. These microenviromental stresses lead to the induction of autophagy, resulting in the build-up of AA

within autolysosomes. The PAT1-containing nutrisome (Figure 1) is well placed to utilise these luminal nutrients to maintain a residual level of mTORC1 activity and maintain homeostasis within the cell until conditions improve (reviewed in Goberdhan, 2010). We have previously shown in vivo in flies that when PI3K signalling is increased, as is the case in the majority of human cancers, the growth-promoting properties of the PATs are enhanced. PATs, which are normally distributed between intracellular membranes and the cell surface, become more intracellular in these conditions, a trafficking process that is required for increased growth (Ögmundsdóttir et al., 2012). I will present data showing that PI3K is also involved in PAT regulation in colon cancer cell lines, particularly under stress conditions.

I will also discuss the analysis we have performed using IPTG-inducible shRNA constructs targeting PAT4 in HCT116 tumours using in vitro and xenograft models. Combined with expression studies in human tumour samples, this work suggests a role for PAT4 in tumour progression.

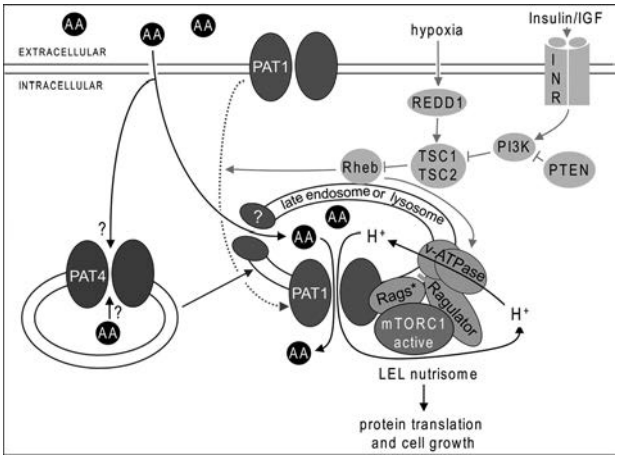

Figure 1 | Schematic model shows the PAT1 protein complex that we have identified in HEK-293 cells and dubbed the 'nutrisome'. This is formed on LELs following stimulation of cells with extracellular amino acids (AAs). AA stimulation also leads to the rapid build-up of AA within LELs via an unknown mechanism. Components of the nutrisome, namely the activated Rag heterodimer (Rags*), pentameric Ragulator, PAT1 and v-ATPase proton pump are required for mTOR to shuttle to LELs to form active mTORC1 and promote cell growth. Cycling of protons through the nutrisomal engine or binding of AA to PAT1 may lead to conformational changes in the complex that activate mTORC1. PI3K/Akt/Rheb signalling regulates endocytosis of the PATs in flies and may also regulate PAT1 (dotted arrow) subcellular localisation. PAT4, like PAT1, is required for AA-stimulated mTORC1 activation and cell proliferation, but its subcellular localisation is currently unclear.

The role of heterodimeric transporters in cancer cell growth

Y. Kanai

Division of Bio-system Pharmacology, Department of Pharmacology, Osaka University Graduate School of Medicine, Osaka, Japan

Heterodimeric transporters belong to SLC7 cationic amino acid transporter/glycoprotein-associated family. They are composed of single membrane-spanning glycosylated heavy chains and non-glycosylated multiple membrane-spanning light chains. The light chains are catalytic subunits responsible for substrates transport, whereas the heavy chains are accessory subunits that form complexes with the light chains via a disulfide bond and assist the membrane localization of the heterodimeric complexes. In addition to the roles in membrane sorting of the transporters, one of the heavy chains 4F2hc (4F2 heavy chain; CD98hc; SLC3A2) is involved in multiple protein-protein interactions and generates growth signals presumably through the interactions with integrins. The substrates of such heterodimeric transporters are in general amino acids. Among the heterodimeric transporters, LAT1 (SLC7A5) and xCT (SLC7A11), both of which form heterodimers with 4F2hc, have been demonstrated to be upregulated in cancers. LAT1, as described bellow, mediates uptake of the large neutral amino acids for cellular nutrition and mTOR signaling, whereas xCT is responsible for the uptake of cystine for cellular glutathione production to protect cells from oxidative stress. The upregulation of xCT in cancer stem cells has been reported to be responsible for the resistance to drug and radiation therapy.

In terms cellular metabolism, amino acid transporters mediate cellular uptake of amino acids for cells to growth and survive. They are regulated to keep up with the metabolic status so that living cells take up amino acids depending on the metabolic requirements. In tumor cells, amino acid transporters are upregulated to support massive protein synthesis for continuous growth and proliferation. Among amino acid transporters expressed in tumor cells, system L transporters have been proposed to be crucial to supply tumor cells with large neutral amino acids including many essential amino acids. Among them, LAT1 (L-type amino acid transporter 1) is highly expressed in human malignant tumors. In contrast, cells in normal tissues express other amino acid transporters including the other isoform of system L transporter LAT2. We have found

that the high expression of LAT1 in tumors is correlated with poor prognosis. Thus, LAT1 can be a molecular target for the diagnosis of cancers. In fact, many radiolabeled amino acid probes used for bio-imaging and diagnosis of cancers are the substrates of LAT1. Among them, 18F-FAMT (L-[3-18F]-alpha-methyltyrosine) is selective for LAT1 and an excellent probe in positron emission tomography (PET) for the diagnosis of cancers. Different from 18F-FDG (fluorodeoxy glucose) conventionally used for PET diagnosis of cancers, 18F-FAMT is specific to cancers and not accumulated in non-cancerous legions. Additionally, 18F-FAMT can be applied to brain tumors because the brain background is low in 18F-FAMT PET.

Because LAT1 is upregulated in tumor cells to support continuous growth and proliferation, the inhibition of LAT1 is expected to suppress cancers. We have examined the effect of inhibition of LAT1 on tumor growth and found that a classical system L inhibitor, 2-aminobicyclo-(2,2,1)-heptane-2-carboxylic acid (BCH), and an antisense oligonucleotide designed against LAT1 inhibits the proliferation of tumor cells and suppressed the growth of tumors subcutaneously inoculated to nude mice. In agreement with this, the inhibition of LAT1 by BCH and the antisense oligonucleotide prolongs the survival of tumor-bearing mice. In order to design the LAT1-specific high-affinity inhibitors, we examined the properties of substrate recognition by LAT1. We found that LAT1 relies on the ionic interaction with alpha-carboxyl group and alpha-amino group and on the hydrophobic interaction with the substrates. Based on this, we designed chemical compounds and obtained LAT1 inhibitors with an affinity ~1,000 fold higher that that of BCH. They effectively suppressed tumor growth in vivo and in vitro at lower doses compared with those for BCH. These observations conclude that LAT1 is essential for cancer cell growth and progression of cancers. Additionally, it is proposed that the inhibition of LAT1 could be a new rationale to anti-tumor therapy.

In cancer cells, LAT1/4F2hc forms further molecular complexes with other membrane proteins such as integrins, CD147 and amino acid transporter ASCT2. ASCT2 mediates the influx of glutamine and assists the influx of essential amino acids including leucine through LAT1 via exchange mechanism. Such "transportsome" is essential for the activation of mTOR signaling in cancer cells. In the lecture, the role of LAT1/4F2hc heterodimeric complex in cancer cell growth will be discussed in terms cellular signaling originated from both LAT1 and 4F2hc.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA304

The role of monocarboxylate transporters in cancer microenvironment

F. Baltazar

Life and Health Sciences Research Institute (ICVS), School of Health Sciences, University of Minho, Braga, Portugal and ICVS/3B's - PT Government Associate Laboratory, Braga/Guimarães, Portugal

One essential hallmark of tumour cells is altered metabolism (1). Most tumour cells exhibit high rates of glycolysis, even in the presence of oxygen ("Warburg effect"), resulting in increased production of lactate, which is transported out of the cells, contributing to the acidic microenvironment encountered in tumours. The acidic microenvironment has been associated with invasive behaviour, mutagenesis as well as radio- and chemoresistance (2). More recently, several authors have proposed a metabolic complementarity between tumour and stroma. If the tumour is glycolytic, the associated stroma is more oxidative and vice-versa. The latter process is known as the "reverse Warburg effect" (3).

Monocarboxylate transporters (MCTs), by performing the plasma membrane efflux of lactate coupled with a proton, especially the isoforms 1 (MCT1) and 4 (MCT4), play an important role in the maintenance of the metabolic phenotype of tumours and associated stroma. MCT1 has been more associated with cells exhibiting an oxidative phenotype, being involved in lactate uptake, while MCT4 has been associated with the glycolytic phenotype, being responsible for lactate efflux (4).

Our group has been studying the expression of these MCT isoforms as well as their chaperone, CD147, essential for MCT activity and plasma membrane expression, in several series of human cancers (5). We found upregulation of MCT1 and MCT4 colorectal cancer, upregulation of MCT1, MCT4 and CD147 in cervical cancer, upregulation of MCT1 in breast cancer and upregulation of MCT1 and CD147 in glioblastomas, compared to the corresponding non-neoplastic tissues. On the other hand, there was downregulation of MCT4 in gastric cancer and downregulation of MCT1 in prostate cancer. We also found important associations between MCT overexpression and the clinicopathological data of the cases, mostly with aggressiveness parameters. Due to their role in the maintenance of tumour metabolism, MCTs are considered promising targets in cancer therapy. Thus, we are also studying the effects of MCT inhibition using different tumour models. In general, MCT inhibition in glycolytic tumour cells leads to a decrease in lactate production, cell proliferation, migration and invasiveness (6).

In summary, MCT activity is essential for the maintenance of the metabolic phenotype of tumours, playing a key role in the crosstalk between tumour cells and microenvironment. However, MCTs are differentially expressed among the solid tumours and future strategies of MCT inhibition in cancer treatment should take this fact into account.

SLC6A14 as a drug target for cancer therapy

V. Ganapathy, M. Thangaraju, P.D. Prasad, V. Coothankandaswamy and Y. Bhutia

Biochemistry and Molecular Biology, Georgia Regents University, Augusta, GA, USA

"Starve the tumor cells to death" - A novel therapeutic approach with a logical basis: Rapid growth is a hallmark of cancer, a feature that places increased demand for nutrients. Entry of nutrients into tumor cells is enhanced by upregulation of specific transporters; these transporters have potential as drug targets for cancer therapy. If we can interfere with the entry of essential nutrients into tumor cells, we should be able to starve these cells to death. If the transporters that are specifically induced in tumor cells compared to normal cells are identified, blocking the function of the induced transporters would have potential as a logical therapeutic strategy for cancer treatment. Since normal cells don't depend on these transporters for survival, cell death induced by such a strategy would be tumor-specific, with little off-target effects.

Amino acid nutrition in cancer: Tumor cells have an increased need for amino acids to support protein/nucleotide synthesis. Mammalian cells cannot synthesize essential amino acids; they must obtain these amino acids via specific transporters. Glutamine, though a non-essential amino acid, is critical for tumor cells. Tumor cells are addicted to glutamine ("glutamine addiction") and metabolize glutamine through a novel pathway known as "glutaminolysis" (1). Amino acids are also coupled to cell signaling via the mammalian target of rapamycin (mTOR), which integrates signals from growth factors, energy status, and amino acid nutritional status, and coordinates these signals with cell growth (2). Inhibitors of mTOR are in clinics for cancer treatment. Amino acid deprivation in tumor cells would also be expected to interfere with mTOR signaling.

SLC6A14 as a novel drug target for treatment of cancer: Mammalian cells express ~40 amino acid transporters that are expressed in different combinations in a cell type-specific manner. Among them, one transporter stands out as unique based on its functional features. It is SLC6A14 (3). It transports all essential amino acids as well as glutamine. It is exceptionally concentrative, coupled to a Na+ gradient, a Cl- gradient, and membrane potential. It is expressed at low levels in normal tissues, but is induced in colon cancer (4), cervical cancer (5), estrogen receptor (ER)-positive breast cancer (6), and pancreatic cancer. Tumor cells upregulate SLC6A14 to meet their increased demand for essential amino acids and glutamine, indicating that SLC6A14 drives their "glutamine addiction." Therefore, blocking the function of this transporter would starve these tumor cells to death. We have shown that this indeed is the case. Down-regulation of SLC6A14 in colon cancer cells, ER-positive breast cancer cells, and pancreatic cancer cells with shRNA suppresses the growth of these cells in mouse xenografts. We have also identified α-methyl-L-tryptophan (α-MLT) as a selective blocker of SLC6A14. α-MLT induces amino acid starvation and death in SLC6A14-positive cancer cells in vitro and inhibits their growth in mouse xenografts. The growth of SLC6A14-negative cancer cells is not affected under similar conditions, demonstrating lack of off-target effects. The blockade of SLC6A14 induces cell death in SLC6A14-positive tumor cells by three different mechanisms: it prevents the entry of essential amino acids, it targets the "glutamine addiction" behavior, and it inhibits mTOR (7). We have recently generated Slc6a14-null mouse. The mouse is viable and fertile, suggesting that SLC6A14 is not essential for normal tissues. Since cancer cells selectively induce SLC6A14 to meet their increasing demands for amino acids, we predicted that deletion of Slc6a14 would provide protection against cancer. This indeed is the case.

α-MLT could be used as a drug in clinical trials for treatment of colon cancer, pancreatic cancer, cervical cancer, and ER-positive breast cancer. It can also serve as a lead compound for development of new and more potent anti-cancer drugs targeting SLC6A14. Another strategy is to develop monoclonal antibodies against SLC6A14 with ability to block the transporter function. Such biologicals would also be effective in the treatment of SLC6A14-positive tumors in a manner similar to the currently used cancer therapies with monoclonal antibodies targeting EGF receptor, VEGF receptor, and HER2.

SLC6A14 is not a universal drug target for all cancers. Some cancers, e.g., ER-negative and triple-negative breast cancers, do not upregulate SLC6A14 and therefore will not respond to blockers of the transporter. But success of our studies demonstrating SLC6A14 as a viable drug target for colon cancer, cervical cancer, pancreatic cancer, and ER-positive breast cancer provides a rational basis for identification of new amino acid transporters as drug targets for other types of cancers because the SLC6A14-negative cancer subtypes must upregulate some other amino acid transporters to support their growth.

Behavioural ecology of the gut

T. Piersma, A. Dekinga, A. Bijleveld, T. Oudman and J.A. van Gils

Marine Ecology, NIOZ Royal Netherlands Institute for Sea Research, Den Burg, Netherlands

We look at the gut as the biggest interface between an organism and its environment. Guts are responsive to many external conditions (food availability, pathogen pressure and nutritional demands), whilst at the same time serving internally orchestrated seasonal fitness functions. In our work on the ecology and evolution of shorebirds, i.e. seasonal migrants that travel the length and with of the globe but with distinct habitat preferences, we have taken the gut as a consequential and fully integrated part of the organism-environment interaction. We will review how different parts of the gut respond to changes in food quality and demand, even representing strategic design solutions to challenges and habitats encountered next. Our prime example are molluscivore specialists (especially red knots, Calidris canutus) that in some conditions trade a hard-shell-processing against a food-toxin constraint. A novel level of organismal integration is suggested by the finding that personality differences between individuals correlate with gut size in seemingly adaptive ways.

Flexibility of the gut during the neonatal period: does it have consequences later in life?

G. Boudry

INRA UR 1341 ADNC, St-Gilles, France

Early life nutrition impacts durably several physiological and metabolic functions and is a risk factor for the development of metabolic disease in adults (obesity, type 2 diabetes, hypertension, ...). This theory of nutritional imprinting or Developmental Origin of Health and Disease established by Barker in the late 80's (1) has been reinforced by experimental data on organs and tissues directly involved in the pathophysiology of the metabolic syndrome (liver, adipose tissue, pancreas...) (2). The gut has got little attention in this context so far. Yet, evidences for a role of the gut in the pathophysiology of metabolic diseases in adults, especially with gut microbiota and barrier function maladaptation to a high fat diet, have emerged (3-4). The structure of the gut microbiota is established and the mucosal immune system programed in early life. This postnatal development is not hard-wired and is influenced by environmental and nutritional factors. Man can hypothesize that this flexibility in acquisition of the microbiota and education of the gut immune system in early life would be long-lasting and induce distinct response to a high fat diet later in life. There are already several evidences that early life environmental factors including stress such as maternal deprivation or chemical contaminants such as bisphenol A dramatically impact adult response to gut inflammation or visceral painful stimuli in models of inflammatory bowel disease and irritable bowel syndrome. Recently, evidences have also emerged that nutritional factors, including energy, fat and fatty acids, protein, and micronutrients imbalances during early life have remnant effects of gut function in adults with alterations in microbiota, intestinal barrier function and/or defense systems. Examples of such long-term effects on the gut will be provided, focusing on piglet model and adaptation to a high fat diet. Those emerging data challenges neonatal nutrition which, apart from its traditional role as a supplier of building blocks for growth, may play another, yet potentially crucial role in shaping the individual's future life, impinging on the risk of disease decades later on.

Diverse feeding regimes and gut flexibility in ectotherms

S. Secor

Department of Biological Sciences, University of Alabama, Tuscaloosa, AL, USA

Animals exhibit a wide diversity of feeding habits, within which exists a broad continuum of feeding frequencies and feeding patterns. At one end of the continuum are small endotherms that seemingly are continuously digesting to maintain their high metabolic rates, whereas at the opposite end of the spectrum are large ectotherms that as a function of their foraging habits and low energy demands, feed relatively infrequently. In addition, many animals experience each year an extended period of fasting due to the lack of food, harsh conditions, or the conflicting demands of reproduction. Driven by very predictable long episodes of digestive quiescence and the elevated cost of maintaining an active gut, selection would favor the down regulation of GI performance during such fasting periods. Consequently, such an adaptive response would require the capacity to rapidly upregulate GI function with feeding. While such examples of phenotypic flexibility are prevalent across vertebrate taxa, the most striking cases are observed for ectotherms, especially snakes. Studies with snakes have identified a remarkable adaptive interplay between feeding habits and the capacity to regulate intestinal form and function. Species of snakes that feed infrequently in the wild (e.g., pythons, boas, and rattlesnakes) experience with the completion of digestion the downregulation of intestinal hydrolase and transporter activities and atrophy of the intestinal epithelium. Feeding triggers the immediate upregulation of intestinal function and rapid hypertrophy of the epithelium. In contrast, snakes that feed relatively frequently in the wild (i.e., many colubrids) experience only modest regulation of intestinal form and function with feeding and fasting. These snakes, as is the case for many other vertebrates, maintain an active gut between meals. Significant modulation of intestinal structure and function with fasting and feeding have likewise been observed for fishes and amphibians, the latter best exemplified by species that aestivate during dry seasons. The cellular mechanism largely responsible for this dichotomy in intestinal response resides with the extent that the microvilli

modulate their surface area. Fasting triggers a rapid shortening of the intestinal microvilli for infrequently feeding snakes, with is reversed with feeding. The 5-fold changes in microvillus length and surface area with fasting and feeding match the magnitude of change of intestinal function. Frequently feeding snakes do not alter microvillus length with feeding, and hence do not experience any significant change in function. Examined for the Burmese python is that feeding triggers a very rapid genomic response; evident by the more than 2000 intestinal genes whose expression are significantly regulated with feeding. A close examination of the adaptive interplay between snake feeding habits and gastrointestinal regulation reveal two caveats, that feeding habits of snakes are highly phylogenetically conserved and that feeding frequency is spread over a broad continuum. Hence, modes of digestive response may be dictated by phylogeny, rather than as adaptations, and species with intermediate feeding habits or that exhibit interpopulation variation in feeding habits, may experience intermediate or alternative mechanisms of digestive response. Preliminary data for boas suggest that feeding habits trumps phylogeny in determining the mode of intestinal response to feasting. Early exploration of the intestinal response of the generalist feeding viperid, the water moccasin (*Agkistrodon piscivorus*), has found modest regulation of intestinal morphology across populations. Driven by the fitness-based selection of optimizing energy, animals have evolved the integrative machinery to alter gastrointestinal performance based on the periodicity and magnitude of digestive demand.

SA309

Assessing the interplay between digestive flexibility and community structure in a Neotropical fish assemblage

N. Vidal, N. Zaldúa, A. D'Anatro and D. Naya

Universidad de la Republica, Montevideo, Uruguay

Phenotypic plasticity has been suggested as the main mechanism for species persistence under a global environmental change scenario (e.g., Charmentier et al. 2008; Deutsch et al. 2008). However, standard models aimed to predict the effect of climatic change on species distribution do not allow for the inclusion of differences in plastic responses among populations. This is mainly because we still lack quantifications of plasticity for several traits in several populations for each species to be modelled. An encouraging pathway that could bring closer our ability to made realistic predictions on species persistence with the pace of current environmental changes, is the identification of general patterns in phenotypic plasticity, which could be easily incorporated into the models (Molina-Montenegro and Naya 2012). In line with this, several studies analyzing latitudinal patterns in phenotypic plasticity have been published in the recent years (Naya et al. 2008; Kellerman et al. 2009; Molina-Montenegro and Naya 2012). However, very few studies have evaluated phenotypic plasticity at the local community level, considering, for example, plastic responses in an entire species assemblage (but see Peacor et al. 2012). In addition, no one of them has addressed the relationship between phenotypic plasticity and basic community structure attributes, such as species trophic habits, body mass and relative abundance. Within this context, here we assessed seasonal flexibility and flexibility during short-term fasting in digestive organs size for an entire fish assemblage, comprising ten species, four trophic levels, and a 37-fold range in body mass. Specifically, we were aimed to test the following hypothesis: (1) Given that species occupying lower trophic levels mainly consume resources that are abundant all year round (e.g., detritus, periphyton), while species occupying higher trophic levels typically predate on resources that markedly change in abundance between seasons f(e.g., insects, fish larvae); we predict a positive relationship between seasonal digestive flexibility and trophic position; (2) Given that food intake rates scale with body mass with an exponent lower than one (typically between 0.66 and 0.75), while organs size scale with body mass isometrically; we predict a negative relationship between digestive flexibility during fasting and body size; (3) Given the potential impact of digestive flexibility on organisms' fitness, we predict that more flexible species, both in a seasonal and short-term basis, should have greater relative abundances than less flexible species. In agreement with our predictions, we found that: (1) Seasonal flexibility in intestinal length was correlated with species trophic position, as could be expected from seasonal changes in species diet composition and energetic demands; (2) Flexibility during fasting in intestine and liver dry masses were inversely correlated with body size, as expected from scaling relationships; (3) Flexibility in intestinal mass, both seasonal and during fasting, was positively correlated with species relative abundance. In summary, our study identified three interesting trends in digestive flexibility in relation to community structure attributes, which represent an encouraging departure point in the search of general patterns in plasticity at the local community scale. The fact that rare species were the less flexible is, however, worrisome under the current scenario of global environmental change.

Host-gut microbe symbioses and adaptation to dietary change

H.V. Carey

Comparative Biosciences, University of Wisconsin, Madison, WI, USA

The vertebrate gut is home to trillions of microbes that have evolved complex, mutualistic relationships with their hosts. The microbiota has profound and diverse effects on animal development and physiology (McFall-Ngai et al., 2013), perhaps best exemplified in the gastrointestinal tract which has been shaped through evolution to achieve a tolerant, cooperative relationship with gut symbionts. Host diet is a major factor that influences the diversity and abundance of the microbiota. To meet their metabolic needs, most gut microbes (in non-ruminant animals) utilize dietary components that have escaped small intestinal digestion and absorption. Certain host-derived substrates, such mucin glycans and nutrients in shed epithelial cells, can also be metabolized. Our recent studies have focused on the role of gut microbiota in shaping seasonal flexibility in gastrointestinal structure and function in hibernating mammals. As in other seasonal hibernators, 13-lined ground squirrels undergo a distinct annual cycle that prepares them for the physiological extremes that occur during the winter months. After emergence in spring when body mass is at a nadir, ground squirrels fatten through summer and fall, and then gradually reduce food intake and activity until emergence into burrows. Food intake ceases once hibernation begins and metabolism shifts to a primary reliance on lipids for fuel. Although periods of extended fasting are a normal and necessary component of the annual hibernation cycle, they have the potential to compromise gastrointestinal integrity. The absence of enteral nutrients, particularly in species that do not fast on a regular basis, can reduce expression of brush border enzymes and nutrient transporters and increase intestinal permeability, which elevates the risk of bacterial translocation. In contrast, species that hibernate display a remarkable degree of adaptive flexibility in gut structure and function that minimizes adverse changes during winter fasting. Seasonal cycles of feeding and fasting can also impact the relationship between hibernators and their resident gut microbes. In 13-lined ground squirrels, the microbiota associated with luminal contents undergoes seasonal restructuring during the hibernation season that reflects shifts in taxonomic groups that rely to varying degrees on dietary vs. host-derived substrates (Carey et al., 2013). Although microbial metabolism is largely suppressed during the low body temperatures of winter torpor, periodic arousals to euthermia provide sufficient time for microbial degradation of endogenous substrates, resulting in production of short-chain fatty acids that can be utilized by the host. Seasonal flexibility in host characteristics likely contributes to maintenance of a mutually beneficial, tolerant state. For example, several features of the intestinal immune system, which is the primary sensor of gut microbes and their metabolites, are modified during hibernation in a manner indicative of altered host-microbe signaling in the absence of inflammation or pathologic immune cell infiltration (Kurtz and Carey, 2007). Enterocytes in hibernating squirrels increase expression of the tight junction protein occludin, which may help to restrict paracellular movement of bacterial metabolites in the setting of a "leakier" gut (Carey et al., 2012). Mucin protein expression also rises shortly after hibernation begins, which is important because the mucus layer both protects the host epithelium from microbial invasion and provides metabolizable substrates for microbial proliferation. Mucus production in the hibernator gut may be particularly important for the mucosa-associated microbiota, a population that resides adjacent to the epithelium in the mucus layer. Our recent studies indicate that the mucosal microbiota undergoes some of the same seasonal trends as seen in the luminal population, e.g., reductions in relative abundance of Firmicutes taxa and increases in abundance of Bacteroidetes and Betaproteobacteria. Phylogenetic diversity across the annual cycle is highest and lowest in microbiotas of spring and late winter squirrels, respectively. Together, these studies emphasize that investigation of gastrointestinal flexibility in animals should incorporate the potential contributions of gut microbes, which can have profound effects on their hosts beginning at birth and extending into adulthood through recurring seasonal events that affect the host-microbial symbiosis.

Architecture and dynamics of native AMPA receptors in the mammalian brain - insights from functional proteomics

B. Fakler

University of Freiburg, Freiburg, UK

AMPA-type glutamate receptors (AMPARs) are central players in the mammalian brain crucial for a variety of processes including fast excitatory neurotransmission, synapse development and activity-dependent synaptic plasticity that underlies learning and memory.

As a key to this pronounced diversity in physiological functions, we have recently provided the first comprehensive analysis of architecture and composition of native AMPARs using novel high-resolution proteomic technologies. Thus, AMPARs in the adult rodent brain are multi-protein complexes of previously unanticipated complexity that are assembled from a pool of 34 different constituents. The majority of these constituents, mostly secreted proteins or transmembrane proteins of different classes, have not yet been related to AMPAR function.

Using the newly building blocks of native AMPARs we have started to analyze the significance of this molecular framework for the complex role of AMPARs in excitatory synaptic transmission.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA312

TARP interplay and the regulation of Ca^{2+}-permeable AMPA receptors: lessons from *stargazer* mice

C. Bats[1], D. Studniarczyk[1], D. Soto[1,2], M. Farrant[1] and S.G. Cull-Candy[1]

[1]Neuroscience, Physiology and Pharmacology, University College London, London, UK and [2]Laboratori de Neurobiologia – IDIBELL, Barcelona, Spain

While GluA2-containing calcium-impermeable AMPA receptors (CI-AMPARs) are widely expressed in the central nervous system, the expression of GluA2-lacking calcium-permeable AMPA receptors (CP-AMPARs) is more restricted - they are only found in a subset of neuronal and glial cells or at specific developmental stages. These CP-AMPARs play an important role in the physiology of the brain. Not only do they contribute to basal transmission, but they are also essential to normal development and synaptic plasticity. On the other hand, the over activation or upregulation of CP-AMPARs, has been linked to diverse neurological disorders, including hypoxic/ischemic damage to neurons and glia, chronic pain and drug addiction. As the relative contribution of CP-AMPARs to synaptic transmission is critical in both physiological and pathological processes, it is of interest to understand the molecular mechanisms underlying their regulation. Transmembrane AMPAR regulatory proteins (TARPs) enhance both AMPAR expression and channel function. With this in mind, we asked whether these auxiliary subunits play a role in the differential trafficking of CP- and CI-AMPARs.

Much of our knowledge of TARP/AMPAR interactions comes from work on cerebellar granule cells, neurons that normally express only CI-AMPARs. Like granule cells, cerebellar stellate cells express TARPs γ-2 and -7, but contain both CP- and CI-AMPARs. We have examined AMPAR subtype distribution in these two cell types, using patch-clamp recording. In particular, we have considered which TARPs are involved in the synaptic and extrasynaptic expression of different AMPAR subtypes, using the spontaneous mutant mouse *stargazer*.

Experiments on *stargazer* played a central role in the discovery of TARPs as essential components of the native AMPAR complex. These ataxic mice lack TARP γ-2 and display a characteristic loss of AMPAR-mediated currents at mossy fiber-to-granule cell synapses. This is associated with a near complete absence of surface AMPARs. Closer examination has demonstrated that, γ-2 not only promotes the delivery of AMPARs to the plasma membrane, but also enables the clustering of surface AMPARs at synapse by specifically interacting with PDZ-containing proteins of the postsynaptic scaffold (PSD-95). Six functional TARPs have been identified, according to their ability to rescue AMPAR-mediated EPSCs in *stargazer* granule cells - TARPs γ-3, -4, -and -8 (which are closely related to γ-2), and the atypical TARPs, γ-5 and -7. The latter interact physically and functionally with AMPARs but fail to restore synaptic transmission in *stargazer* granule cells. Each of these six TARPs displays distinct, partially overlapping, patterns of expression in the brain. However, it has generally been assumed that only one TARP subtype is present within a given AMPAR complex. TARP γ-2 and -7 are enriched within the cerebellum, where they co-cluster at synaptic contacts **[1]**. Importantly, no other TARP is expressed in cerebellar granule cells, which would explain why these neurons are particularly susceptible to the loss of γ-2 in *stargazer* mice.

Unlike granule cells, stellate cells in *stargazer* mice still display AMPAR-mediated EPSCs. However, we find that the contribution of CI-AMPARs to these synaptic currents is dramatically decreased **[2]**. This implies that CP-AMPARs, unlike CI-AMPARs, can cluster at synapses in the absence of γ-2, or any other typical TARPs. Surprisingly, while functional γ-7-associated CP-AMPARs are present at the surface of *stargazer* stellate cells, EPSCs are mediated by TARPless CP-AMPARs. Whereas it was believed that γ-7 simply fails to compensate for the lack of γ-2 in *stargazer* granule cells, we show that γ-7 prevents AMPAR surface expression and synaptic clustering, as knocking-down γ-7 rescues synaptic currents. Our observations indicate that the loss of surface AMPARs in *stargazer* granule cells lacking γ-2 is caused by the absence of CP-AMPARs and a suppressive effect of γ-7 .

Together our results suggest that the relationships between AMPARs and TARPs, and between typical and atypical TARPs, are more complex than originally thought, and that there is still much to learn from *stargazer* mice about AMPAR trafficking.

SA313

TARPs as major molecular determinants for expression and heterogeneity in synaptic AMPA receptors

M. Watanabe

Anatomy, Hokkaido University Graduate School of Medicine, Sapporo, Japan

To ensure reliable synaptic transmission, AMPA receptors are anchored in the postsynaptic density via PSD-95 and transmembrane AMPA receptor regulatory proteins (TARPs). The TARP family comprises six isoforms: four classical (g-2, g-3, g-4, and g-8) and two atypical (g-5 and g-7) TARPs. Their spatial distributions are distinct in the brain, but multiple TARPs are expressed in given neural regions (Fukaya et al., 2005). We have so far studied synaptic expression of individual TARPs, and pursued their roles in AMPA receptor expression by using mutant mice defective in TARP genes. In the cerebellum, TARPg-2 and g-7 are the major isoforms in two major cerebellar neurons, i.e., granule cells and Purkinje cells. They are selectively localized on the postsynaptic membrane of excitatory synapses, and synergistically promote synaptic expression of AMPA receptors. Most notably, GluA2 and GluA3 subunits are severely lost at Purkinje cell synapses in g-2/g-7-double knockout mice, and AMPA receptor-mediated currents at climbing fiber synapses are reduced to 10% of the wild-type levels (Yamazaki et al., 2010). TARPg-7 is also expressed in Bergmann glia, and substantial loss of GluA1 and GluA4 expressions occurs in Bergmann glia of g-7-knockout mice. These observations indicate that TARPs are the major

molecular determinants for expression of neuronal and glial AMPA receptors. It should be noted that synaptic expression of AMPA receptors undergoes target cell type-dependent and input source-dependent regulation. This is best known in the hippocampus, where TARPg-8 is the major TARP with additional expression of TARPg-2 and g-3 (Fukaya et al., 2006). To specify the role in the target cell type-dependent regulation, we have recently tested three types of Schaffer collateral synapses in the hippocampal CA1, i.e., perforated and non-perforated synapses on pyramidal cell spines and dendritic synapses on parvalbumin-positive interneurons. In the symposium, we will present our molecular-anatomical data suggesting that TARPg-2 is more potent than TARPg-8 in producing the heterogeneity of AMPA receptor contents among the Schaffer collateral synapses.

Modulation of AMPA receptor function by CamKII and stargazin

A. Kristensen

Drug Design & Pharmacology, Københavns Universitet, København Ø, Danmark, UK

AMPA-selective glutamate receptors are ligand-gated cation channels that mediate fast excitatory neurotransmission in the brain and thus mediate many aspects of brain function including cognition, movement, learning and memory. The function and number of postsynaptic AMPA receptors is dynamically regulated by a number of cellular mechanisms to control synaptic strength, a key feature of cellular models of learning and memory such as long-term potentiation. The function, trafficking and synaptic signaling of AMPA receptors containing the GluA1 subunit is tightly regulated by phosphorylation. Ca2+/calmodulin-dependent kinase II (CaMKII) phosphorylates the GluA1 AMPA receptor subunit at Ser831 to increase single-channel conductance. We show that CaMKII increases the conductance of native AMPA receptors in mouse hippocampal neurons through phosphorylation of Ser831 located in the intracellular C-terminal domain. Dissection of the molecular mechanism underlying CamKII modulation of conductance reveal that transmembrane AMPA receptor regulatory proteins (TARPs) play an critical role for allowing for phospho-Ser831 to increase conductance of heteromeric GluA1-GluA2 receptors; a main AMPA receptor subtype in hippocampal neurons. Phosphorylation of Ser831 increases the efficiency with which each subunit can activate, thereby increasing the likelihood that more receptor subunits will be simultaneously activated during gating. The molecular basis for this regulation is currently unknown. Present work evaluating the mechanism by which GluA1 phosphorylation influences AMPA receptor function include studies of intra- or interprotein interactions in AMPA receptor C-terminal that may be modulated by TARPs and GluA1 phosphorylation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

A nanoscale view into the dynamic of AMPA receptor organization in synapses

D. Choquet

IINS, Bordeaux, France

Ionotropic AMPA glutamate receptors (AMPAR) mediate fast excitatory synaptic transmission in the central nervous system. Using a combination of high resolution single molecule imaging techniques and video-microscopy, we have previously established that AMPARs are not stable in the synapse as thought initially, but undergo continuous entry and exit to and from the post-synaptic density through lateral diffusion.
Single molecule approaches give access to the full distribution of molecule behaviors and overcome the averaging intrinsic to bulk measurement methods. They allow access to complex processes where a given molecule can have heterogeneous properties over time. We will present some recent developments in single molecule imaging technologies and their application to track single molecules in live neurons.
We have recently found a new function for this fast diffusion in controlling fast synaptic transmission. Upon consecutive synaptic stimulation at high frequency, synaptic transmission is depressed. This depression shapes the frequency dependent adaptation of individual synapses. AMPAR lateral diffusion allows fast exchange of desensitised receptors with naïve functional ones within or nearby the post-synaptic density. This participates to the recovery from depression in the tens of millisecond time range, in parallel with recovery from desensitization.
In addition, we now show that the Ca2+/Calmodulin-dependent protein kinase II (CaMKII), which is critically required for the synaptic recruitment of AMPA-type glutamate receptors

(AMPARs) during both development and plasticity, induces the synaptic trapping of AMPARs diffusing in the membrane. Furthermore, this CaMKII dependent AMPAR immobilization regulates short term plasticity. Thus, NMDA dependent Ca2+ influx in the post-synapse trigger a CaMKII and Stargazin dependent decrease in AMPAR diffusional exchange at synapses that controls synaptic function.

Activity patterns and synaptic development in the mammalian retina

D. Kerschensteiner

Washington University School of Medicine, Saint Louis, MO, USA

The developing retina generates spontaneous waves of activity that propagate up to primary visual cortex and guide the synaptic refinement of early visual circuits. Across several species, retinal waves mature in three stereotypic stages (I – III), in which different circuit mechanisms give rise to activity patterns with unique spatiotemporal properties. In the final stage (III), glutamate release from bipolar cells drives retinal waves that sequentially recruit neighboring retinal ganglion cells with opposite light responses (ON and OFF RGCs). I will discuss recent insights from our group into the circuit mechanisms of stage III waves. Using systematic combinations of dual patch clamp recordings we reconstructed the sequence of neuronal activation during stage III waves, identified intersecting lateral excitatory and vertical inhibitory networks that propagate and pattern this activity, and characterize the mechanisms of communication among neurons in these circuits. In addition, I will describe our findings on the influence of glutamatergic activity on the synaptic development of bipolar cells, highlighting novel cell-type-dependent and retrograde plasticity mechanisms.

Signal from noise: properties and homeostasis of retinal waves

M.H. Hennig

School of Informatics, University of Edinburgh, Edinburgh, UK

Neural activity in the neonatal mouse retina consists of spontaneous, correlated bursts originating from neighbouring retinal ganglion cells (RGCs), resulting in propagating waves. It is well established that the properties of retinal waves change during the course of development as the retinal network slowly assembles. Through computational modelling, we have recently found that early-stage waves (around P5 in the mouse), which depend on cholinergic synaptic transmission, reflect a very specific network state that maximises the variability of the activity patterns. I will present new recordings of mouse retinal waves at near-cellular resolution with a 4,096-channel multielectrode array, which confirm the predicted high variability of early-stage waves, and also reveal relatively low RGC recruitment. The recordings also show that waves become slower and smaller when GABAergic signalling matures (P6-7). Glutamatergic waves (P10 onwards), in contrast, are denser and begin to show repetitive trajectories confined to few localized hotspots that gradually tile the retina. Finally, I will show that some key properties of early-stage waves are under homeostatic control, but not after GABAergic signalling has matured. Taken together, these findings suggest that the role of retinal waves may change over development. Early-stage waves are very robust and appear well suited to signal broad topographic order and drive eye-specific segregation in RGC target areas, while late-stage waves appear to activate neurons in a more compact and localised manner.

From how to make a hair cell tick to orchestrating auditory development: action potentials in the immature cochlea

C.J. Kros

School of Life Sciences, University of Sussex, Brighton, UK and Dept of Otorhinolaryngology, UMCG, Groningen, Netherlands

In the mature cochlea, inner hair cells (IHCs) signal the reception of sound by means of graded receptor potentials with rapid kinetics. Before the onset of hearing, which occurs at about postnatal day 12 in small altricial rodents such as mice, rats and gerbils, the IHCs fire spontaneous action potentials with mean frequencies in the order of one Hz instead (Kros et al 1998; Johnson et al 2011). Developmental changes in ion channel expression along the basolateral membrane of the IHCs, mainly the replacement of a slow delayed-rectifier potassium current, $I_{K,neo}$, with a fast BK current, $I_{K,f}$ and changes in the Ca^{2+}-dependence of neurotransmitter release, underlie this switch in function (reviewed by Kros 2007).

Speculation about the possible roles for these spontaneous action potentials includes that they may be important for the correct maturation of the IHCs and their innervation, which undergoes considerable change between birth and the onset of hearing. Another potential function is that spontaneous activity may be required for the refinement of tonotopic maps to enable frequency analysis, in the IHCs themselves or further along the auditory pathway. A number of recent findings is beginning to provide some evidence. The action potential pattern is found to vary as a function of location of the IHCs along the cochlea, so that immature apical IHCs fire action potentials in bursts, whereas basal IHC fire more randomly (Johnson et al 2011). Within the bursts of the apical IHCs the frequency of the action potentials is similar to that of the randomly firing action potentials in the base, but the overall mean frequency is lower in the apex. This might in principle serve as a signal that could be used to set up a tonotopic gradient. The bursts in the apical-coil IHCs depend on release of acetylcholine (ACh) by the efferent terminals hyperpolarizing the IHCs via SK2 channels closely coupled to the ACh receptors, whereas the firing of the basal-coil IHCs depends on hyperpolarization by ATP, again via SK2 channels coupled to P2X receptors (Johnson et al 2011). ATP is released in waves in the immature postnatal cochlea from supporting cells situated to the modiolar side of the IHCs (Tritsch et al 2007).

Another useful finding is that, at least in the second postnatal week, action potential firing is inferred to depend on the mechano-electrical transducer current that flows when the hair bundle is at rest (Johnson et al 2012), i.e. in the absence of sound stimulation (which does not reach the inner ear yet at this stage of development). This may explain why IHCs of mice with mutations that affect the function of proteins in the mechanosensitive hair bundle, such as myosin 6 and myosin 7a, fail to mature into fully functional auditory hair cells (myosin 6: Roux et al 2009; myosin 7a: Roberts, Ranatunga and Kros in preparation). The absence of a resting transducer current might prevent action potential activity in these cases, leading to a failure of maturation of the IHCs.

Challenging questions remain. For example, what causes the developmental failure of outer hair cells (OHCs), which in the myosin 7a mutants fail to express their characteristic KCNQ4 potassium current $I_{K,n}$ (Roberts, Ranatunga and Kros in preparation)? OHCs are not generally thought to fire spontaneous action potentials during development. Would this developmental programme have to be repeated if fully functional mature hair cells are to be regenerated in the mammalian cochlea? Since spiral ganglion cells already exhibit intrinsic spontaneous activity at embryonic day 14 (E14) in mice (Marrs and Spirou 2012), well before that of the IHCs starts at E17.5 in the base and E18.5 in the apex, it would be interesting to investigate their respective roles in the functional maturation of the auditory pathway.

SA319

Characterization of efferent inputs to the inner hair cells before hearing onset

I. Roux

Otolaryngology - Head and Neck Surgery, The Johns Hopkins School of Medicine, Baltimore, MD, USA

In vivo recordings show that cochlear afferent neurons fire bursts of action potentials from P0 on (1), about two weeks before hearing onset in rats. This 'spontaneous' activity of the auditory nerve fibers is driven by glutamate release from inner hair cells (IHCs), that themselves can fire spontaneous calcium action potentials. By analogy to retinal development, it has been suggested that such a spontaneous activity may promote the survival and functional maturation of auditory neurons and guide the refinement of synaptic connections in the auditory brainstem (for review see (2)). Different mechanisms have been shown to contribute to IHCs depolarization. Those include the release of ATP from supporting cells, which drive bursts of action potentials in auditory nerve fibers for most of the postnatal, pre-hearing period (3). Resting level of activation of the mechanotransduction channels, present in the sensory cells from post natal day 1 to post natal day 3 (P1/P3) on, may also contribute to the IHCs depolarization. Interestingly, P0 is also the age at which the cholinergic efferent axons originating in the superior olive complex, are first observed in close vicinity to the IHCs and seem to make initial contact ((4), for review see (5)). Here, I will present recent results obtained using *ex vivo* whole cell recordings, immunohistochemistry and imaging, which demonstrate a 'developmental switch' whereby the hair cell's cholinergic response changes from excitatory to inhibitory during synapse formation. Thus, as in vertebrate skeletal muscle, the nicotinic acetylcholine receptors (nAChRs), most likely formed by α9 and α10 nAChRs subunits (6), are functional and present in the sensory hair cell plasma membrane before synapses are formed. Then, in a second step, nAChRs clustering, coupling to calcium-dependent small conductance potassium channels (SK2) and synaptic currents appear, suggesting that efferent synaptic function is contemporaneous with, and may require, SK2 channel expression, a hypothesis consistent with the lack of functional efferent activity reported in SK2 knockout IHCs (7).

Calcium signalling in the developing cochlea: insight from mouse models of deafness

F. Mammano

Venetian Institute of Molecular Mediicine, Foundation for Advanced Biomedical Research, Padua, PD, Italy and Department of Physics and Astronomy, University of Padua, Padua, PD, Italy

Cellular rhythms are ubiquitous at all levels of biological organization and involve biochemical oscillations that modulate the concentration of key metabolic substrates and second messengers. Among these, rhythmic variations in the cytosolic free calcium concentration have been shown to arise spontaneously or after stimulation by hormones or neurotransmitters. In the developing cochlea, ATP-dependent calcium oscillations occur in non-sensory cells of the lesser epithelial ridge either as a consequence of intercellular calcium wave propagation or due to sustained ATP stimulation in the submicromolar range [1]. Spontaneous calcium oscillations in the lesser epithelial ridge are rarely observed in cochlear organotypic cultures at room temperature, but their frequency is drastically increased upon blockade of ectonucleotidases, a manipulation that highlights the tonic release of ATP from these cells [2]. On the contrary spontaneous calcium transients are always observed in the greater epithelial ridge, in a class of non-sensory cells (first described by Koelliker) which transiently populate the sensory epithelium from the spiral limbus to the inner hair cells. Spontaneous calcium transients in these cells have been attributed to release of ATP through connexin hemichannels [3, 4]. We recently demonstrated that cochlear non-sensory cells of the lesser and the greater epithelial ridge share the same PLC- and IP_3R-dependent signal transduction cascade activated by ATP. Furthermore, we found that: (a) phosphatidylinositol phosphate kinase type 1γ is primarily responsible for the synthesis of the PIP_2 pool in the cell syncytia that support auditory hair cells; (b) spatially graded impairment of this signalling pathway in cochlear non-sensory cells causes a selective alteration in the acquisition of hearing [5]. Previous studies had noted that ATP-dependent calcium oscillations in non-sensory cells of the cochlea feed-back on connexin expression and participate in the coordinated regulation of connexin 26 and connexin 30 through NF-κB (nuclear factor kappa-light-chain-enhancer of activated B cells). We extended those findings demonstrating that connexin 26 and connexin 30 are both targets and effectors of calcium signalling in the developing cochlea. Altogether, these experiments have highlighted a crucial link in cochlear non-sensory cells between the expression and function of connexin 26 and connexin 30, ATP release, calcium waves, periodic calcium transients and NF-κB signalling networks, but other calcium-dependent transcription factors used by non-excitable cells may be involved. Clarifying the pathogenesis of sensorineural hearing loss and deafness due to connexin dysfunction (DFNB1, DFNA3; http://hereditaryhearingloss.org/) is just one aspect of the problem. The other critical issue is discovering appropriate treatments. Gene delivery with vectors derived from recombinant adeno-associated viruses has been successfully explored as a means to restore connexin expression and rescue intercellular coupling and calcium signalling in cochlear organotypic cultures from connexin-knockout mice with defective expression of connexin 26 and connexin 30 [6, 7]

Mechanism and regulation of DHHC S-acyltransferases

M. Linder, B.C. Jennings and J. Lai

Molecular Medicine, Cornell University, Ithaca, NY, USA

Protein S-palmitoylation is a reversible posttranslational modification of proteins with palmitate or other long-chain fatty acids. In the last five years, improved proteomic methods have increased the number of proteins identified as substrates for palmitoylation from tens to hundreds. Palmitoylation regulates protein membrane interactions, activity, trafficking, and stability and can be constitutive or regulated by signaling inputs. A family of protein acyltransferases or PATs is responsible for modifying proteins with palmitate or other long-chain fatty acids on the cytoplasmic face of cellular membranes. The signature feature is a DHHC (Asp-His-His-Cys)-cysteine rich domain that is the catalytic center of the enzyme. The biomedical importance of members of this family is underscored by their association with intellectual disability, Huntington's Disease, and cancer in humans and raises the possibility of the enzymes as targets for therapeutic intervention. Accordingly, elucidating the mechanism and regulation of the DHHC pro-

teins is important for understanding how palmitoylation manifests in physiology and pathophysiology.
Our recent work has focused on the enzymology of DHHC PATs, addressing the mechanism of palmitate transfer to substrate and the quaternary structure of the enzymes. DHHC proteins acylate themselves upon incubation with palmitoyl-CoA, a process termed autoacylation. Both autoacylation and transfer of palmitate to substrate are dependent upon the cysteine within the DHHC motif. It has been suggested that autoacylation of the enzyme represents a transient acyl-enzyme transfer intermediate. To directly test this hypothesis, we performed single turnover assays with DHHC2 and DHHC3 and demonstrated that a radiolabeled acyl group on the enzyme transferred to the protein substrate, consistent with a two-step ping-pong mechanism. Enzyme autoacylation and acyltransfer to substrate displayed the same acyl-CoA specificities, further supporting a two-step mechanism.
Evidence suggests that mutation of the catalytic cysteine within the DHHC motif results in a protein that acts as a dominant negative (Fukata M. et al. (2004); Fang C. et al. (2006). However, the mechanism by which the mutation interferes with the function of the wild type protein is unknown. One hypothesis is that DHHC proteins function as oligomers and that mixed oligomers of wild type and mutant enzyme are inactive. Support for this argument comes from coimmunoprecipitation experiments that suggest that DHHC3 forms homomultimers and heteromultimers with DHHC7 (Fang C. et al. (2006). We sought to determine whether DHHC proteins oligomerize in cells and in vitro. Bioluminescence resonance energy transfer experiments revealed that DHHC2 or DHHC3 self-associate when expressed in HEK-293 cells. Purified DHHC3 resolved as a monomer and dimer on blue native polyacrylamide gels. In intact cells and in vitro, catalytically inactive DHHC proteins displayed a greater propensity to form dimers. BRET signals were higher for the catalytically inactive DHHC2 or DHHC3 than their wild type counterparts. DHHC3 BRET in cell membranes was decreased by the addition of palmitoyl-CoA, a treatment that results in autoacylation of the enzyme. Cross-linking of purified DHHC2 reversibly inhibited its activity in vitro. The correlation of enzyme activity with the monomeric species suggests that oligomerization may represent a mechanism to regulate enzyme activity.

SA322

Palmitoylation and the control of cardiac ion transporters

W. Fuller

Cardiovascular Division, University of Dundee, Dundee, UK

In excitable tissues, the activity of plasmalemmal ion transporters is vital for the maintenance of normal electrical activity and ion gradients. In cardiac muscle, the transarcolemmal Na gradient established by the ubiquitous Na/K ATPase (Na pump) is essential not only for generating the rapid upstroke of the action potential but also for driving a number of ion exchange and transport processes critical for normal cellular function, ion homeostasis and the control of cell volume (1). The cardiac sodium calcium exchanger (NCX1), which is functionally coupled to the Na pump, similarly plays a vital role in the regulation of trans-sarcolemmal Ca fluxes in cardiac muscle, because it is the principal route by which Ca leaves the cell during diastole (2). Inappropriate NCX1 function contributes to cardiac contraction abnormalities and heart failure: reduced NCX1 activity reduces Ca removal and impairs relaxation, whereas overactive NCX1 unloads the intracellular Ca stores and impairs systolic function.
Curiously, a common feature of regulation of both the Na pump and NCX1 is controversy regarding the roles and targets of protein kinases in their regulation. Phosphoregulation of NCX1 is an unresolved controversy. In the heart, phosphoregulation of the Na pump is now established to be through phosphorylation of the accessory protein phospholemman (PLM). Unphosphorylated PLM inhibits the Na pump, and phosphorylation by PKA (at S68) or PKC (at S63, S68 and T69) activates the pump (1).
As well as being phosphorylated, PLM is palmitoylated at two cysteines, C40 and C42 in an intracellular α-helix adjacent to its transmembrane domain. Palmitoylation of PLM inhibits the Na pump, but intriguingly palmitoylation of PLM is promoted by its phosphorylation at S68 by PKA (3). Hence one post-translational modification of PLM that activates the Na pump promotes a second, which inhibits it. Although the DHHC-PAT(s) that palmitoylate PLM (or any pump subunits - see below) are yet to be identified, another important regulator of the palmitoylation status of PLM is the redox state of the cell. Cellular glutathione status is linked to PLM palmitoylation state by the anti-oxidant protein peroxiredoxin 6, which depalmitoylates PLM in a glutathione dependent manner. In addition, mitochondrial redox stress leads to a reduction in PLM palmitoylation, with a concomitant increase in its glutathionylation at C42. The presence of PLM (or other members of the FXYD gene family to which it belongs, which are also palmitoylated) in the Na pump enzyme complex therefore provides a means to link pump activity to cellular redox / metabolic state, through a balance between its phosphorylation, palmitoylation, and glutathionylation. Interestingly, we find palmitoylation of PLM is reduced in a mouse model of cardiac hypertrophy induced by ligation of the thoracic aorta, highlighting that the contribution of ion transporter palmitoylation to the development of cardiovascular diseases is a research area of considerable promise.
We have recently undertaken proteomic profiling of protein palmitoylation in ventricular muscle. A considerable number of cardiac ion channels, transporters and ion transport regulators are palmitoylated, including NCX1 and the plasma membrane Ca ATPase PMCA1 (the two routes for Ca efflux during diastole), the Na pump catalytic α and regulatory β subunits, voltage gated Na channel pore-forming and regulatory subunits, and voltage gated Ca channel pore-forming and regulatory subunits. Although the sites and functional effects of palmitoylation of these transporters are still to be fully defined, it is strikingly significant that every route of entry and exit of Na and Ca into and out of cardiac myocytes is palmitoylated. Since palmitoylation may directly regulate spatial organisation as well as ion channel / transporter activity, the role of palmitoylation in the acute and long term co-ordination of cardiac sarcolemmal Na and Ca fluxes, and therefore excitation-contraction coupling and cardiac contractility may prove as significant as any post-translational modification investigated to date.

Direct imaging of palmitoylated PSD-95 in neurons

M. Fukata and Y. Fukata

National Institute for Physiological Sciences, Okazaki, Japan

Precise regulation of protein assembly at specialized membrane domains is essential for diverse cellular functions including synaptic transmission. However, it remains unclear how protein clustering at plasma membranes is initiated and controlled. Protein palmitoylation, a common reversible lipidation, regulates protein targeting to plasma membranes. Such modified proteins are enriched in these membrane domains. To enable visualization of this dynamic process, we selected a recombinant antibody that specifically recognizes the palmitoylated conformation of PSD-95, a major postsynaptic scaffold protein. When used as a GFP-tagged antibody in living neurons, it revealed that endogenous palmitoylated PSD-95 is partitioned into multiple discrete clusters in a dendritic spine. Membrane-inserted PSD-95 palmitoyltransferase, DHHC2, catalytically generates and maintains these subspine membrane domains, which serve as anchoring positions for AMPA-type glutamate receptors. Thus, the palmitoylating enzyme at plasma membranes creates highly localized hotspots of protein palmitoylation and directly marks sites where specific proteins concentrate to organize membrane domains.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA324

Palmitoylation and trafficking of peripheral membrane proteins

L.H. Chamberlain

SIPBS, University of Strathclyde, Glasgow, UK

Palmitoylation, the attachment of fatty acids (predominantly palmitate) onto cellular proteins, has emerged as a widespread post-translational modification of both transmembrane and peripheral membrane proteins. Recent breakthroughs in the palmitoylation field came with the discovery of the "DHHC" protein family that collectively regulate cellular palmitoylation dynamics; at least 24 of these DHHC proteins are encoded in the human genome. I will discuss how the interaction of specific DHHC isoforms with peripheral membrane protein substrates is encoded. In addition, I will discuss how multiple palmitoylation of individual peripheral membrane proteins affects their intracellular trafficking and dynamics in normal and disease states.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Human circadian rhythms, melatonin and metabolism

D.J. Skene[1], J.E. Ang[2], K. Ackermann[3], M. Kayser[3], B. Middleton[1], S. Davies[1], V.L. Revell[1], A.E. Thumser[1], J.D. Johnston[1] and F.I. Raynaud[2]

[1]Faculty of Health and Medical Sciences, University of Surrey, Guildford, UK, [2]Cancer Research UK Cancer Therapeutics Unit, Division of Cancer Therapeutics, The Institute of Cancer Research, Sutton, UK and [3]Department of Forensic Molecular Biology, Erasmus MC University Medical Center Rotterdam, Rotterdam, Netherlands

The circadian timing system drives the cyclic processes observed in most physiological processes including sleep/wake and metabolic function. The mammalian circadian system comprises a master clock located in the hypothalamic suprachiasmatic nuclei (SCN) and peripheral clocks found in most body tissues. For optimal functioning correct temporal coordination between the central SCN clock and peripheral clocks is maintained via feedback/feed forward neuroendocrine and autonomic mechanisms. The environmental light/dark cycle is the primary time cue synchronising the human circadian timing system to 24 h.

Recent research has demonstrated links between circadian clocks and metabolism, and between sleep deprivation/sleep restriction, circadian desynchrony and metabolic disorders. Our current studies aim to investigate the mechanisms underlying these interactions between circadian timing, sleep and metabolism. Measuring the human circadian timing system has traditionally relied on assessment of circadian rhythms driven by the central SCN clock, such as melatonin, cortisol and core body temperature. Of these SCN-driven rhythms, the timing of the melatonin rhythm is considered the most reliable marker of circadian phase and numerous studies have used the melatonin profile to assess circadian rhythmicity and phase in healthy and diseased individuals in laboratory and field studies.

Studying circadian regulation of metabolism and assessing the relative importance of photic and non-photic time cues (e.g. food, exercise, sleep/wake behaviour) for entrainment, however, also requires reliable markers of peripheral clocks in humans. For example, it might be that food is a major entrainer of peripheral clocks in humans, as has been demonstrated in animals.Early studies reported clock gene expression in peripheral blood cells and buccal tissue. Gene expression in peripheral blood mononuclear cells (PBMCs) shows 24 h rhythms which are driven by the circadian clock1 and can be phase shifted by appropriately timed light2. Our recent data show that the core clock mechanism in peripheral leucocytes is compromised during acute sleep deprivation3. During one night of total sleep deprivation expression of the clock gene BMAL1 was suppressed and the heat shock gene HSPA1B expression was induced. Some clock gene rhythms showed reduced amplitude during sleep deprivation (CRY1, CLOCK, DBP) while other high-amplitude clock gene rhythms (e.g. PER1-3, REV-ERBα) remained unaffected.

For metabolism-clock studies, serial sampling of human adipose tissue offers promise. We have recently demonstrated

robust 24 h rhythms in gene expression in this metabolically active tissue in three experimental groups: lean, obese-non-diabetic and obese-Type 2 diabetic groups4. Nocturnal plasma melatonin concentrations were significantly higher in obese-non-diabetic subjects compared to weight-matched Type 2 diabetic subjects ($p < 0.01$) and lean controls ($p < 0.05$), whereas there was no difference in the amplitude or timing of leptin rhythms between the three experimental groups5.

Elucidation of the mechanisms linking metabolic disease and circadian clock misalignment, however, will require a global "systems" approach in order to identify the metabolites, genes and proteins driving endogenous circadian rhythms and how factors such as sleep/wake, light/dark, food and posture impact on these. Metabolomics is the untargeted investigation of small molecule metabolite profiles that provides a novel and powerful tool, which may provide a better representation of functional phenotype than changes in DNA, RNA and proteins. We have recently established an untargeted liquid chromatography–mass spectrometric (LC-MS) method to measure metabolite rhythms in human plasma6. In healthy volunteers, a total of 1069 metabolite features were detected and 203 (19%) showed significant time of day variation. Of these, 34 metabolites were identified using a combination of accurate mass, tandem MS, and online database searches. These metabolites include corticosteroids, bilirubin, amino acids, acylcarnitines, and lysophospholipids. Defining time of day variation in the human metabolome, in addition to increasing our understanding of daily metabolic pathways, will be crucial for the future applied use of metabolomics in the detection and treatment of human disease.

Molecular and cellular circuits underlying circadian rhythms of behavior

A. Sehgal

University of Pennsylvania, Philadelphia, PA, USA

We use the fruit fly, Drosophila melanogaster, as a model to understand the molecular underpinnings of behavior and physiology. Like mammals, Drosophila have a sleep state that is controlled by circadian and homeostatic mechanisms. The homeostatic system drives the need to sleep while the circadian system ensures that sleep occurs with a ~24 hour rhythm. The molecular and cellular networks underlying these two types of regulation are distinct and yet they also intersect. Over the year, we and others have identified molecular components of the clock and also molecules required to transmit time-of-day signals form the clock to produce rhythmic sleep:wake. We have also identified genes that regulate sleep, and the cellular site of action of some of these genes. In recent work, we have been mapping the cellular circuits that give rise to rhythmic behavior. Cells that are part of the central clock have been well-studied, but those that receive signals from clock cells and transmit time-of-day signals to produce the overt behavioral rhythm are not known. Using a combination of genetic and anatomical approaches, we have identified some of these cells, and are addressing the connections between them. Together these studies are expected to lead to an understanding of how circadian and homeostatic regulation are integrated to produce sleep:wake cycles.

Systems and synthetic biology of biological timings

H.R. Ueda

Laboratory for Systems Biology and Functional Genomics Unit, Center for Developmental Biology, RIKEN, Kobe, Hyogo, Japan and Laboratory for Synthetic Biology, Quantitative Biology Center, RIKEN, Kobe, Hyogo, Japan

The logic of biological networks is difficult to elucidate without (1) comprehensive identification of network structure, (2) prediction and validation based on quantitative measurement and perturbation of network behavior, and (3) design and implementation of artificial networks of identified structure and observed dynamics.

Mammalian circadian clock system is such a complex and dynamic system consisting of complicatedly integrated regulatory loops and displaying the various dynamic behaviors including **i**) endogenous oscillation with about 24-hour period, **ii**) entrainment to the external environmental changes (temperature and light cycle), and **iii**) temperature compensation over the wide range of temperature. In this symposium, I will take a mammalian circadian clock as an example, and introduce the systems- and synthetic-biological approaches for understanding of biological timings.

SA328

Circadian rhythms and seasonal adaptation

D. Weinert

Institute of Biology/Zoology, Martin-Luther-University, Halle, Germany

Seasonal acclimation is associated with various behavioral and physiological changes, allowing animals to cope with different climatic conditions and food availability. These changes are timed by the annual photoperiodic cycle. In some species, it entrains an endogenous circannual rhythm to a period of 1 year. In other species, the photoperiodic cycle directly drives the seasonal changes in a given function (or at least one of the transitional phases of this function). Whatever the underlying mechanism is, it enables the organism to prepare for rather than merely react to cyclic events in the environment.
Most organisms use circadian oscillators to measure length of day and, in mammals, the suprachiasmatic nuclei (SCN) play a crucial role. These structures receive photic stimuli via the retino-hypothalamic tract and encode information about photoperiod via modification of clock gene expression and reorganization of neuronal networks. The resulting signal, in turn, regulates pineal melatonin synthesis and release. It is mainly the duration of the melatonin signal that provides the information about photoperiod and the direction (lengthening or shortening) of its change. This hormone is secreted at night and transported to various target sites where the signal is "decoded". The duration of secretion is inversely related to day length.
In Djungarian hamsters (Phodopus sungorus) of our breeding stock, a certain number of animals show a delayed activity onset (DAO) which is caused by a diminished ability to photic synchronization. Other hamsters show arrhythmic activity patterns (AR) because the SCN as the main circadian oscillator does not generate a circadian signal. Since, a functional circadian system is a prerequisite for photoperiodic time measurement the question arose, what consequences these deteriorations may have for seasonal adaptation.
When animals of the different rhythmic phenotypes were transferred to short day (SD) conditions (L:D = 8:16 h), none of the DAO and AR hamsters displayed any SD trait. Only wild type (WT) hamsters did respond properly. Their activity time expanded, body mass and testes size decreased, and fur coloration changed from summer to winter pelage. Only a small number of hamsters did not respond, a phenomenon that has been described before. Possibly, this is of adaptive significance, as these animals may reproduce late in the year if the environmental conditions are suitable. Non-responding hamster, we also found under natural lighting and temperature conditions. Moreover, these animals did not display daily torpor, a state that was regularly observed in responders. This way, hamsters do save energy under conditions of low outdoor temperature. The times of torpor onset and offset are under circadian control.
When DAO hamsters were kept in constant darkness (DD), they exhibited typical short-day traits like lengthening of activity time, reduction of body mass and testes size, and change of fur coloration. Since, under these conditions, non-parametric light effects inducing phase responses are absent, activity-onset and activity-offset (~evening and morning oscillators) may change according to the oscillators' intrinsic period lengths. Both are >24 h, but the period of the evening oscillator is shorter than that of the morning oscillator, and this is the reason for the expansion of activity time in DD. The decompression may cause a longer melatonin signal and, subsequently, the short-day traits that were obtained. By contrast, AR animals did not display any SD response even after 14 weeks in DD. Obviously they are incapable of measuring photoperiodic time due to a complete disruption of circadian rhythmicity. Their SCN do not generate a circadian rhythm.
The results show physiological mechanisms necessary for seasonal adaptation are working in DAO hamsters and that it is the inadequate interaction of the LD cycle with the SCN that prevents the photoperiodic reaction. The signal released by the SCN and sent to the pineal is not consistent with the photoperiod. As a consequence of this disruption in the circadian system, the pattern of melatonin synthesis does not reflect the length of night appropriately. We have shown that the circadian melatonin rhythm in DAO hamsters kept under long day conditions correlates with their delayed activity-onset; a similar pattern might be expected when these hamsters are kept in SD.
In summary, one may conclude that only animals with a functional circadian system, the WT hamsters, can respond properly to changes of the photoperiod and, thus, adapt to seasonal variations in the environment. Hamsters of the other two phenotypes not only lack the ability to synchronize with the 24-h day, but also the capability of photoperiodic time measurement.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Circadian rhythms in hypometabolic models – lessons learnt from an animal with unique wintering strategies

O. Thalmann[1], D. Wegmann[2], S. Hasan[1], T.A. Pulikotial[3], H. Lohi[3], S. Saarela[4] and K. Herzig[4]

[1]Department of Biology; Genetics, University of Turku, Turku, Finland, [2]University of Fribourg, Fribourg, Switzerland, [3]University of Helsinki, Helsinki, Finland and [4]University of Oulu, Oulu, Finland

Unraveling the various mechanisms that facilitate adaptive processes in nature is a pivotal challenge uniting evolutionary biologists, physiologists, ecologists and scientists from many diverse fields. While over the past decades, we have acquired comprehensive knowledge about the physiological, immunological or morphological modifications that allow species to adapt and thrive in natural environments, their underlying genetic mechanisms remain mostly unknown. With recent advances in molecular technologies we are now - for the first time - able to investigate genetic changes that play key-roles in these fundamental evolutionary processes. Moreover, the rapidly growing number of completely sequenced genomes allows us to find and compare variation in genes, which might represent examples of parallel evolution acting in many diverse taxa.
Here we present preliminary data investigating the adaptive genetic changes in an unusual, hypometabolic model – the raccoon dog (Nyctereutes procyonoides). The raccoon dog is the only member of dog-like mammals (family Canidae) that adopts a passive wintering strategies (shallow winter sleep) in order to survive harsh seasonal weather conditions. By doing so, the animal reduces its metabolic rate to a minimum and relies upon its stored energy resources, which it mostly gained before transforming into the hypometabolic state. Vast metabolic changes are required to undergo the physiological fluctuations associated with this wintering strategy and identify-

ing the genetic mechanisms underlying these processes has importance for our understanding of winter sleep and hibernation in endothermic mammals in general.
We utilized high-throughput sequencing of the raccoon dog's transcriptome to identify genes responsible for the species' unique metabolism. The sampling consisted of normalized cDNA extracted from a pool of diverse tissues such as liver, brain, kidney and fat tissue of one female and one male raccoon dog. The millions of sequenced nucleotides were assembled into approx. 26,000 contigs and mapped against all protein coding genes extracted from the fully sequenced genome of a close relative, the dog. Subsequently, we generated a multispecies alignment of orthologous genes present in seven different species: raccoon dog, dog, three hibernators (bat, hedgehog and squirrel) and two non-hibernating control species (human, cow). We developed a model that utilizes the genetic distances between a quartet of species including one hibernator, the raccoon dog, the dog and a non-hibernating outgroup to identify genes that show more similarity between the raccoon dog and any of the hibernators than to its evolutionary relative the dog. Our model identified a suite of candidates that might play a key-role in metabolic processes facilitating wintering strategies of endothermic mammals and we currently investigate those genes in more depth by means of analyzing the patterns of selection acting upon them and characterizing the causal mutations.
Notably, our model is also generally applicable to future projects that aim at testing other traits or genes for signals of parallel evolution.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA330

The renin-angiotensin system in cardiovascular progenitor cells

A. Roks

Internal Medicine, Erasmus Medical Center Rotterdam, Rotterdam, Netherlands

Modulation of the renin-angiotensin system, in particular of the function of the hormones angiotensin II and angiotensine-(1-7), is an important target for pharmacotherapy in the cardiovascular system. In the classical view, such modulation affects cardiovascular cells to decrease hypertrophy, fibrosis, and endothelial dysfunction, and improves diuresis. In this view, excessive stimulation of angiotensin II type 1 receptors fulfills a detrimental role, as it promotes cardiovascular pathogenesis, and this is opposed by stimulation of angiotensin II type 2 and the angiotensin-(1-7) receptor coded by the Mas proto-oncogene. In recent years, this view has been broadened with the observation that the renin-angiotensin system regulates bone marrow stromal cells and stem cells, thus involving hematopoiesis and tissue regeneration by progenitor cells. This change of paradigm has enlarged the field of perspectives for therapeutic application of existing as well as newly developed medicines that alter angiotensin signaling, and now stretches beyond cardiovascular therapy. In the present lecture the role of angiotensin II and angiotensin-(1-7) and their respective receptors in hematopoietic and mesenchymal stem cells is reviewed and the latest findings with respect to Ang-(1-7) are discussed as well as possible pharmacotherapeutical implications.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The (Pro)renin receptor in neurogenic hypertension

W. Li[1], H. Peng[1], A. Ichihara[2] and Y. Feng[1]

[1]Tulane University, New Orleans, LA, USA and [2]Medicine II, Tokyo Women's Medical University, Tokyo, Japan

The brain renin-angiotensin system plays an important role in blood pressure (BP) regulation. However, the origin of brain Ang II remains unknown due to the low brain renin activity. We previously reported that prorenin and (pro)renin receptor (PRR) is present in the brain. To test our hypothesis that prorenin mediates Ang II formation in the brain via binding to PRR, the neuron-specific PRR knockout (Nefh-PRRKO) and wild type (WT) mice (n=5/group) were implanted with telemetric probes and intracerebroventricular (ICV) cannulas. BP was recorded in conscious mice during ICV infusion (0.3μl/min) for ten minutes. ICV infusion of Ang II (100ng/μl) increased BP (ΔMAP, mmHg) in both WT (48±5) and Nefh-PRRKO (40±2)mice; and this effect was blocked by AT1 receptor blocker (Losartan) indicating that the AT1R is functionally intact in Nefh-PRRKO mice. ICV infusion of mouse prorenin (100ng/μl) induced a pressor response in WT mice (42.3±5.7), and this response was completely blocked by Losartan or Captopril suggesting that prorenin induced Ang II-dependent pressor response in WT mice. Interestingly, the pressor response to mouse prorenin was abolished in Nefh-PRRKO mice (5±1; $P<0.05$), indicating that prorenin mediates pressor response via binding to PRR. To determine whether PRR contributes to the development of brain RAS-dependent hypertension, Nefh-PRR and WT littermates (N=8/group) were treated with 50mg of deoxycorticosterone acetate (DOCA) subcutaneously, plus 0.9% NaCl drinking water for 21 days. The baseline BP was similar between Nefh-PRR (101 ± 2) and WT (101 ± 3) mice. BP was increased in WT mice (132 ± 6) by DOCA-salt treatment, while Nefh-PRR mice remained normotensive (108 ± 3). In summary, prorenin via PRR mediates AngII/AT1R-dependent pressor response in the brain. Neuron-specific PRR deletion attenuates the development of DOCA-salt hypertension likely due to the lack of Ang II/AT1R activation. We conclude that prorenin/PRR may be the key factors to initiate the brain RAS and play an essential role in neurogenic hypertension.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA332

(Pro)renin receptor functions

G. Nguyen

Early Development and Pathologies", Collège de France, 75231 Paris, France

Since the discovery of the (pro)renin receptor (PRR) much effort was made to establish its role in pathology, hoping to optimize the blockade of the renin-angiotensin system with a PRR blocker. In spite of a positive correlation between a polymorphism of the PRR gene called *ATP6AP2* and higher blood pressure in Japanese and Caucasian subjects, experimental

models failed to clearly establish a link between PRR, hypertension and organ damage. Because complete ablation of the *PRR/ATP6AP* led to embryonic lethality in mice, contrary to all other components of the RAS, more essential cellular function of PRR were suspected. These functions are related to the vacuolar H^+-ATPase (V-ATPase), the ATP-dependent proton pump that acidifies intracellular vesicles lysosome, endosomes and to the Wnt signalling pathways. Indeed, conditional knock-out of PRR in cardiomyocytes and podocytes revealed an essential role of PRR in the assembly and the function of the V-ATPase, leading to impaired vesicles acidification and endocytosis, increased autophagy, cell apoptosis and rapid death of the animal. Moreover, PRR is involved in the Wnt/beta-catenin and Wnt/Planar Cell Polarity signalling pathways that are absolutely critical during embryonic development. It is important to stress that the functions of PRR in the V-ATPase and in Wnt signalling are totally independent of renin and prorenin.
PRR is cleaved intracellularly by furin to generate a soluble form (sPRR) actively secreted in plasma and in urine. sPRR is able to bind renin and prorenin and to activate prorenin. Our results of sPRR determination in plasma show that it is not correlated with age, gender, plasma renin or prorenin.
Altogether, these results indicate that PRR has much broader functions than binding renin and prorenin and they question the role of PRR in patho-physiological states related to the activation of the renin angiotensin system.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA333

Vasoprotective axis of the RAS- a novel target against diabetic retinopathy

Q. Li, A. Verma, P. Zhu, P. Shil, T. Prasad and M. Raizada

University of Florida, Gainesville, FL, USA

Diabetic retinopathy (DR) is the most common diabetic vascular complication. Despite recent advances in therapeutics and management, DR remains the leading cause of severe vision loss in people under age of sixty and there is no cure currently. Existing evidence suggests that hyperactivity of the vasoconstrictive, proliferative, pro-inflammatory, and fibrotic axis [angiotensin-converting enzyme (ACE)/angiotensin II (Ang II)/angiotensin type I receptor (AT1R)] of the renin-angiotensin system (RAS) plays a central role in the pathogenesis of DR. Diabetes induced hyperactivity of RAS contributes to development and progression of diabetic retinopathy by increasing oxidative stress, vascular inflammation and endothelial dysfunction. Nevertheless, inhibitors of this axis have not proven to be effective in the treatment and prevention of DR in several clinical trials. This is likely due to local activation of Ang II formation independent of circulating Ang II, as well as Ang II-independent activation of RAS within ocular tissue that is not affected by classic RAS inhibitors. This is supported by overwhelming evidence that all components of RAS are expressed in various cell types of the retina and the ocular Ang II levels are much higher in vitreous fluids than plasma in patients with proliferative diabetic retinopathy. The recently established vasoprotective axis involving ACE2/Ang-(1-7)/Mas counteracts the traditional proliferative, fibrotic, proinflammatory and hypertrophic effects of the ACE/Ang II/AT1R axis of the RAS. We have shown that all genes of the RAS are locally expressed; establishing the existence of an intrinsic retinal RAS; and DR is associated with impaired balance of local retinal RAS. Increased expression of ACE2/Ang-(1-7) using AAV-mediated gene delivery overcomes this imbalance and confers protection against DR; and these beneficial effects of gene transfer occur without influencing the systemic hyperglycemic status. Thus, strategies enhancing the protective ACE2/Ang-(1-7) axis of RAS could serve as a novel therapeutic target for DR.

Supported by American Diabetes Association, American Heart Association, Research to Prevent Blindness, NIH grants EY021752 and EY021721.

ACE2/Ang (1-7) in ischemic and hemorrhagic stroke

R.W. Regenhardt[1], A.P. Mecca[1], D.A. Bennion[1], M. Liu[1], L.L. Donnangelo[1], D.A. Pioquinto[1], N.A. Patel[1], J.A. Ludin[1], D. Greenstein[1], F. Desland[1], M.K. Raizada[1], M.J. Katovich[2] and C. Sumners[1]

[1]Department of Physiology and McKnight Brain Institute, University of Florida, Gainesville, FL, USA and [2]Department of Pharmacodynamics2, University of Florida, Gainesville, FL, USA

Stroke is a leading cause of death throughout the world, and angiotensin II (Ang II) acting via its type 1 receptors (AT1R) is well known to exert harmful effects in both the ischemic and hemorrhagic forms of this disease. In several cardiovascular diseases, the angiotensin converting enzyme 2/angiotensin-(1-7)/Mas (ACE2/Ang-(1-7)/Mas) axis of the renin-angiotensin system exerts beneficial actions, often in opposition to the deleterious actions of Ang II/AT1R. Therefore we have investigated the potential beneficial actions of the ACE2/Ang-(1-7)/Mas axis in both ischemic and hemorrhagic stroke. Ischemic stroke was induced in Sprague-Dawley (SD) normotensive rats by intracranial injection of endothelin-1 (ET-1; 3 ul of 80 uM) to elicit middle cerebral artery occlusion (MCAO). For this and all other surgical procedures anesthesia was induced using a mixture of oxygen and isoflurane (4%), and was maintained during the procedure with oxygen/isoflurane (2%). Following the surgeries, before waking, rats were administered the analgesic buprenorphine (0.05 mg/kg). Intracerebroventricular (icv) infusion of Ang-(1-7) [1.1 nM; 0.5 ul/h] via osmotic minipumps prior to and during ET-1 induced MCAO elicited significant neuroroprotection, as indicated by a >50% reduction in infarct size and improved performance on behavioral tests. Similar neuroprotection was elicited by icv infusion of the ACE2 activator diminazine aceturate (DIZE; 5 ug/0.5 ul/h) as above. These beneficial effects of Ang-(1-7) and DIZE were abolished by central infusion of the Mas receptor blocker A-779 (1.14 nM; 0.5 ul/h). Importantly, DIZE exerted similar neuroprotective actions when administered systemically post-ischemic stroke. For example, intraperitoneal (IP) injection of DIZE (0.75-7.5 mg/kg) at 4, 24 and 48 h post ET-1-induced MCAO produced significant (~40%) decreases in cerebral infarct size and behavioral deficits, effects that were reversed by icv administered A-779 (1.14 nM; 0.5 ul/h). In stroke prone spontaneously hypertensive rats (spSHR), an animal model of hemorrhagic stroke, icv infusion of Ang-(1-7) as above elicited a significant reduction in the number of striatal hemorrhages and increased the lifespan of these rats. With respect to mechanism, these protective actions of Ang-(1-7)/DIZE were not associated with either altered blood pressure, cerebral

blood flow or (in the case of ischemic stroke) attenuation of ET-1 action. However, Ang-(1-7) administered icv as above exerts anti-inflammatory effects, reducing the increased levels of pro-inflammatory cytokines and microglial activation within cerebral infarct zone following ischemic stroke, and reducing the numbers of microglia within the striatum of spSHR. In vitro studies using microglia isolated from rat cerebral cortex and striatum indicate that Ang-(1-7) (100 nM) decreases activation of these cells and reduces the levels of pro-inflammatory cytokines, confirming an anti-inflammatory action of this peptide. In summary our data indicate that induction of the ACE2/Ang-(1-7)/Mas axis produces powerful anti-stroke actions, and may represent a novel therapeutic avenue for both ischemic and hemorrhagic stroke.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Epigenetics and non-coding RNAs in the regulation of macrophage gene expression

C.K. Glass

Dept. of Cellular & Molecular Medicine, University of California, San Diego, La Jolla, CA, USA

Our recent studies have utilized a combination of genome-wide and genetic approaches to define the molecular mechanisms that underlie the development of classically activated and alternatively activated macrophage phenotypes. These studies suggest a relatively simple model of hierarchical interactions between lineage-determining and signal-dependent transcription factors that are required to select functional cis-active regulatory elements. The majority of these interactions occur at enhancer-like elements that are distant from target promoters. The discovery that these enhancer elements themselves generate transcripts referred to as 'eRNAs' raises a number of interesting new questions regarding the mechanisms underlying enhancer function and therapeutic approaches to modulate macrophage phenotypes.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA336

microRNAs and epigenetic control

A. Zernecke

Department of Vascular Surgery, Technische Universität München, München, Germany

Atherosclerosis is widely appreciated to represent a chronic inflammatory disease of the vessel wall. As part of the inflammatory infiltrate, monocytes/macrophages contribute to the pathogenesis of atherosclerosis. Given the functions of microRNAs as key regulators of cellular functions, such as proliferation, differentiation and cytokine responses, it is conceivable that miRNAs expressed in inflammatory cells would also control disease progression, and circulating miRNAs detected in blood, apoptotic bodies and microvesicles may affect plaque cells and be useful as disease biomarkers. In addition, also epigenetic mechanisms contribute to the regulation of gene expression. We have characterized the expression profile of miRNAs in human plaque tissue and circulation monocyte subsets, and have investigated DNA methylation and corresponding methyltransferases in early and advanced human atherosclerotic carotid lesions and serum of patients with high grade carotid artery stenosis in comparison to healthy individuals. Given the importance of the delicately orchestrated immune response in atherosclerosis, miRNAs expressed in immune cells and epigenetic modifications will likely have profound effects during the evolution of lesion formation and constitute possible targets for therapeutic interventions.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA337

Epigenetics and biomechanical stress responses in cardiac cell biology and disease

F. Sheikh

University of California-San Diego, La Jolla, CA, USA

The biomechanical environment is an important epigenetic factor. Little is known of how biomechanical stress is sensed by the cardiomyocyte sarcomere to transduce intracellular hypertrophic signals and how dysfunction of these pathways may lead to disease. We demonstrate that four and a half LIM domain protein-1 (FHL1) is part of a novel complex within the cardiomyocyte sarcomere, which serves to sense biomechanical stress-induced responses important for cardiac hypertrophy. Fhl1 deficiency in cardiac muscle resulted in a blunted response to hypertrophy and beneficial functional response to pressure overload, induced by transverse aortic constriction. A link to the Galpha-q signaling pathway is shown when Fhl1 deficiency prevents the cardiomyopathy observed in Galpha-q transgenic mice. Mechanistic studies demonstrate that FHL1 plays an important role in the mechanism of pathological hypertrophy by sensing biomechanical stress responses via the stretch sensor domain (titin N2B), which leads to changes in titin and MAPK mediated responses, important for sarcomere extensibility and intracellular signaling. We demonstrate that FHL1 can affect titin N2B expression and mediate changes in muscle compliance that are dependent on titin N2B phosphorylation. We further identify titin N2B as a novel target of ERK2 and demonstrate that a dose-dependent increase in FHL1 interferes with ERK2-mediated titin N2B phosphorylation. These studies identify a novel complex within the cardiomyocyte sarcomere that is critical for biomechanical stress responses in hypertrophy.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Simultaneous optical recording of membrane potential and calcium signals

M. Canepari

Inserm U836, Grenoble, France

Combining voltage and Ca2+ imaging allows correlation of electrical and chemical activity at sub-cellular level. We developed and commercialised an imaging system designed to obtain simultaneous voltage and Ca2+ measurements with

high signal-to-noise ratio from sites as small as a few microns. Using the combination of the commercial voltage sensitive dye JPW1114 and of a UV excitable Ca2+ indicator, these measurements can be obtained with negligible optical cross-talk between the two signals and negligible photo-damage of the preparation. More recently, we started using the recently developed voltage sensitive dye Di-2-ANBDQ(F)PTEA emitting in the IR. This dye can be combined with blue excitable calcium indicators (Calcium Green, Oregon Green or Fluo) permitting the use of simultaneous UV illumination for uncaging. In this presentation I will start showing published results using commercial indicators demonstrating the capability to obtain single-trial resolution from sites as small as 2 microns. I will then present some novel results using a new fast CCD camera permitting acquisitions of both voltage and Ca2+ wavelengths at high speed (up to 20 kHz). This high speed is particularly relevant when using Ca2+ indicators with equilibrium constant > 10 μM which are able to follow Ca2+ signals in less than a millisecond. Thus, using these indicators, it is possible to follow the fast rise time of Ca2+ currents associated with an action potentials and correlate them with local changes of membrane potential. The problem of calibrating optical signals will be also addressed in detail. In summary, the experimental approach presented here opens the gate to many novel physiological investigations requiring simultaneous measurement of voltage and Ca2+ signals.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Voltage imaging from axons and dendritic spines

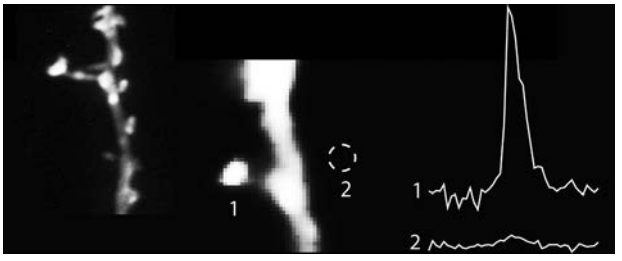
M. Popovic

Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, CT, USA

A central question in neuronal network analysis is how the interaction between individual neurons produces behavior and behavioral modifications. This task depends critically on how exactly are signals integrated by individual nerve cells functioning as complex operational units. Regional electrical properties of branching neuronal processes which determine the input-output function of any neuron are extraordinarily complex, dynamic, and, in the general case, impossible to predict in the absence of detailed measurements. To obtain such measurements one would, ideally, like to be able to monitor, at multiple sites, subthreshold events as they travel from the sites of origin (synaptic contacts on dendritic spines) and summate at particular locations to influence action potential (AP) initiation. It became possible recently to carry out this type of measurements with sub-millisecond and sub-micrometer resolution using multisite recording of membrane potential changes with intracellular voltage-sensitive dyes (Vm imaging). Our method is based on pioneering work on voltage-sensitive molecular probes that report membrane potential changes in transmission and fluorescence light intensity measurements (Cohen and Salzberg, 1978). Many aspects of the initial technology have been continuously improved over several decades (Canepari et al., 2010).

The spatial pattern of Na(+) channel clustering in the axon initial segment (AIS) plays a critical role in tuning neuronal computations, and changes in Na(+) channel distribution have been shown to mediate novel forms of neuronal plasticity in the axon. We took advantage of a critical methodological improvement in the high sensitivity membrane potential imaging technique to directly determine the location and length of the spike trigger zone (TZ) as defined in functional terms. The results show that in mature axons of mouse (postnatal day 18-30) cortical layer 5 pyramidal cells in acute brain slices, action potentials initiate in a region ~20 μm in length centered between 20 and 40 μm from the soma. From this region, the AP depolarizing wave invades initial nodes of Ranvier within a fraction of a millisecond and propagates in a saltatory fashion into axonal collaterals without failure at all physiologically relevant frequencies. We further demonstrate that, in contrast to the saltatory conduction in mature axons, AP propagation is non-saltatory (monotonic) in immature axons prior to myelination in mouse postnatal day 5-9.

The evidence for an important hypothesis that cortical spine morphology might participate in modifying synaptic efficacy that underlies plasticity and possibly learning and memory mechanisms is inconclusive. Both theory and experiments suggest that the transfer of excitatory postsynaptic potential (EPSP) signals from spines to parent dendrites depends on the spine neck morphology and resistance. Furthermore, modeling of signal transfer in the opposite direction predicts that synapses on spine heads are not electrically isolated from voltages in the parent dendrite. To provide direct evidence for the specific question of the transfer of dendritic signals to spine synapses, we further advanced the V(m) imaging technique (Popovic et al. 2012; fig 1) and carried out optical measurements of electrical signals from 4 groups of spines in mouse cortical layer 5 pyramidal cells with different neck length and simultaneously from parent dendrites. The results show that spine neck does not filter membrane potential signals as they spread from the dendrites into the spine heads. The improved Vm imaging technique enabled characterization the transfer of unitary EPSPs from spine synapses across the spine neck to the parent dendrite. A series of measurements showed that the spine/dendrite EPSP amplitude ratio varied from 1 to 4 in different spines.



Improved Vm imaging enables high signal to noise ratio and high spatio-temporal resolution

Membrane potential investigated with voltage sensitive dyes

C. Petersen

EPFL, Lausanne, France

Increasingly deep understanding of the organization of the mouse brain has been facilitated by advances in genetics, electrophysiology and optical techniques together with development of awake head-restrained behaviors. Here, I will present voltage-sensitive dye imaging data correlating neocortical activity with sensorimotor behavior in awake head-restrained mice. In addition, I will discuss optogenetic manipulations specifically perturbing neural activity to gain causal insight. Our data shed new light on the functional organization of sensorimotor cortex, including a surprising direct role for sensory cortex in motor control in the whisker system.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Teasing apart biophysical unpinnings of CNS axon spike kinectics

A.J. Foust

CNRS UMR8154, Université Paris Descartes, Paris, France

The shape of action potentials invading presynaptic terminals, which can vary significantly from spike waveforms recorded at the soma, may critically influence the probability of synaptic neurotransmitter release. Revealing conductances that determine spike shape in presynaptic boutons could bear insights into how dynamic axonal electrochemical milieux modulate synaptic strength, but the small diameter of CNS axon collaterals has prevented direct characterization with traditional electrode recordings.

Voltage imaging has long shown promise for overcoming the low spatial resolution of patch electrode recording; however, low sensitivity previously precluded investigation of phenomena too rapid or too complex to be elucidated with extensive averaging. A recent modification to the fluorescence excitation approach (Holthoff et al., 2010) now enables high signal-to-noise ratio (SNR), single-trial recordings from axons and axon collaterals (Foust et al., 2010, 2011; Popovic et al. 2011).

Utilizing the improved sensitivity of single cell voltage sensitive dye (VSD) imaging, we characterized action potentials propagating through small diameter axon collaterals of pyramidal neurons and interneurons in mouse cortical brain slices with high spatial (1-4 μm) and temporal (0.05-0.1 ms) resolution in single trials. Averaging small numbers of trials (4-8 trials) generated SNRs appropriate for comparing the kinetics of action potentials in different types of cortical neurons. Importantly, the action potentials in the axons of parvalbumin-positive fast spiking interneurons repolarized more quickly than in SOM-positive Martinotti interneurons or excitatory pyramidal neurons. Furthermore, we found that prolonged subthreshold somatic depolarization of layer 5 pyramidal neurons elicited action potential broadening in collaterals and boutons in a distance dependent fashion (Foust et al. 2011).

Lastly, by combining single-cell VSD imaging with pharmacological manipulations, we discovered that Kv1 subunit containing ion channels are important for repolarizing action potentials in cortical pyramidal axon collaterals and en passant presynaptic terminals. Moreover, the spike broadening with depolarization was blocked with Kv1 antagonists, indicating that D-current could play an important role in local graded synaptic transmission (Foust et al., 2011).

Together these findings represent a small sample of new insights to be gained into axonal action potential characteristics and plasticity with high sensitivity single cell voltage imaging.

Membrane potential imaging during functional development of neuronal circuits in vertebrate embryos

Y. Momose-Sato[1] and K. Sato[2]

[1]Department of Health and Nutrition, Kanto Gakuin University, College of Human Environmental Studies, Yokohama, Japan and [2]Department of Health and Nutrition Sciences, Komazawa Women's University, Faculty of Human Health, Tokyo, Japan

Investigating the developmental organization of the embryonic nervous system has been one of the major challenges in neuroscience. Despite their significance, functional studies of the vertebrate embryonic CNS have been hampered, since conventional electrophysiological means have some technical limitations. First, early embryonic neurons are small and fragile, and the application of microelectrodes is often difficult. Second, the simultaneous recording of electrical activity from multiple sites is limited, and as a consequence, spatio-temporal patterns of neural network responses cannot be assessed. The advent of optical techniques using voltage-sensitive dyes has enabled the non-invasive monitoring of electrical activity in living cells and also facilitated the simultaneous recording of neural responses from multiple regions. Using optical recording techniques, it is now possible to follow the functional organization of the embryonic nervous system and to image the spatio-temporal dynamics of the neural network's formation. Here, we present recent progress in optical studies on the embryonic nervous system with special emphasis on methodological considerations and the study of neuronal circuit formation, which demonstrates the utility of fast voltage-sensitive dye imaging as a powerful tool for elucidating the functional organization of the embryonic CNS.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Coronary microvascular network adaptation in a rabbit model of developing heart failure: insights from 3D cryomicrotome imaging

J.P. van den Wijngaard, M.G. van Lier, P. van Horssen, J.A. Spaan and M. Siebes

Biomedical Engineering and Physics, Academic Medical Center, Univ of Amsterdam, Amsterdam, Netherlands

Background: Collateral formation by adaptive microvascular remodeling during chronic myocardial ischemia may ameliorate the development of heart failure. However, little quantitative information is available about potentially protective vascular changes in chronic ischemia leading to heart failure. In this study, we aimed to quantify adaptive changes in chronically ischemic rabbit hearts using high-resolution 3D imaging of the microvascular network. The rabbit heart is known for its lack of innate collateral vessels, while its intermediate size allows assessment of changes in coronary vasculature and transmural perfusion resulting from gradual coronary occlusion.
Methods and Results: New Zealand White rabbits (n=5, male, 2,5-3kg) were anesthetised with a mixture of ketamine (15mg/kg) and dexmedetomidine (0.2mg/kg) with buprenorphine (0.03mg/kg) for analgesia, all i.m.. Anesthesia was maintained by 1.5-3% isoflurane. Regional myocardial ischemia was induced in rabbits by a left thoracotomy and placement of an ameroid constrictor on a side branch of one of the major coronary arteries. Progressive occlusion within 7-10 days produced distal tissue ischemia. A sham-operated animal served as control. Cardiac function was monitored with echocardiography. Post operative, animals received carprofen (4mg/kg i.m.)
After 8 weeks, the animals were sacrificed, the heart was excised and the coronary arteries were filled with fluorescent replica material. Each heart was frozen and alternately cut and block-face imaged at 14 μm slice thickness using a custom-developed imaging cryomicrotome (Spaan et al., 2005). The microvascular structure is clearly visible in the unprocessed image stacks (Fig. 1 A) and replica material can be detected in transmural arteries of up to 50 μm diameter.
Subsequent image processing of the raw images is performed by application of a Hessian based vesselness enhancing algorithm (Sato et al. 1998). Thereby removing the halo around the large coronary arteries and enhancing the small arteriolar structures with low brightness, figure 1B. From the enhanced structure, a topologically representative vascular tree can be reconstructed following the application of a peeling algorithm (Palagyi et al. 1998) reducing the tubular structures to the centerline pixels. From the analysis of the vascular tree skeleton, vascular diameters and collaterals can be obtained, figure 1C (van den Wijngaard et al. 2010).
No signs of myocardial infarction were observed in ischemic hearts, although left ventricular wall thinning was present as compared to the control heart. Computer analysis of the segmented vascular tree identified coronary collateral formation in the ischemic hearts, with collateral connections ranging 50-100 micron between well-perfused territories and the perfusion territory distal to the ameroid constrictor. Few innate collateral anastomoses were detected in the sham operated heart.
Conclusion: With use of 3D episcopic cryomicrotome imaging, coronary microvascular adaptation in ischemic rabbit hearts was demonstrated. Future studies employing fluorescent microspheres will serve to assess regional myocardial blood flow across the ventricular wall in relation to collateral development between the normally perfused and ischemic territories.

Generation of microvascular networks: a biological patterning problem

T.W. Secomb[1,2], J.P. Alberding[2], M.W. Dewhirst[3] and A.R. Pries[4]

[1]Department of Physiology, University of Arizona, Tucson, AZ, USA, [2]Arizona Research Laboratories, University of Arizona, Tucson, AZ, USA, [3]Department of Radiation Oncology, Duke University Medical Center, Durham, NC, USA and [4]Department of Physiology and CCR, Charité - Universitätsmedizin Berlin, Berlin, Germany

Formation of functionally adequate vascular networks by angiogenesis presents a problem in biological patterning. Generated without predetermined spatial patterns, networks must develop hierarchical tree-like structures for efficient convective transport over large distances, combined with dense space-filling meshes for short diffusion distances to every point in the tissue. Moreover, networks must be capable of restructuring in response to changing functional demands without interruption of blood flow. We hypothesize that the problem of vascular patterning is 'solved' by over-abundant stochastic

sprouting angiogenesis in response to a growth factor generated in hypoxic regions (e.g. vascular endothelial growth factor, VEGF), coupled to structural reactions (growth, regression, elimination) of each vessel to mechanical and biochemical stimuli. According to this hypothesis, angiogenesis results in networks with disordered structures, which organize themselves into functional networks through structural adaptation and pruning.
To test this hypothesis and analyze the relations between biological mechanisms and system properties, we developed a theoretical model that integrates simulations of network blood flow, convective and diffusive oxygen transport, generation and diffusion of VEGF, stochastic sprouting angiogenesis, structural adaptation and vessel elimination by pruning. The simulation of structural adaptation of vessel diameters includes information transfer by conducted responses along vessel walls, which is needed for proper flow distribution and avoidance of functional shunts. The model is based on experimental observations of network structure and hemodynamics in rat mesentery, a thin sheet-like tissue.
The model results show that the combination of stochastic angiogenesis stimulated by a growth factor, structural adaptation and pruning in response to hemodynamic and metabolic stimuli is capable of solving the 'problem' of vascular patterning and can generate hierarchical networks with low diffusion distances. To establish and maintain such networks, the following mechanisms are essential: (i) generation of a diffusible vessel growth factor in hypoxic tissue regions; (ii) formation of vessel sprouts in response to above-threshold levels of growth factor; (iii) maintenance of sprouts without pruning before they connect to other vessels; (iv) ability of sprouts to connect with other vessels forming patent flow pathways; (v) diameter adaptation of flowing vessels to hemodynamic and metabolic stimuli and upstream conducted responses; (vi) elimination of redundant vessels by pruning. The model allows assessment of the roles of individual mechanisms in the patterning process and changes resulting from their modification, as may occur in pathological conditions such as tumor growth. Resulting insights may stimulate further experimental investigations of angiogenesis and development of novel therapeutic approaches.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

A microvascular origin of the systemic arterial pressure level

J.B. Jacobsen[1], C.B. Poulsen[2], B.O. Hald[1], N. Holstein-Rathlou[1] and M. Damkjær[3]

[1]University of Copenhagen, Copenhagen, Denmark, [2]Department of Cardiology, Aarhus University Hospital, Aarhus, Denmark and [3]Department of Paediatrics, Kolding Hospital, Kolding, Denmark

The mean arterial pressure (MAP) is relatively invariant across numerous mammalian species despite variation in body mass spanning many orders of magnitude. This suggests that the origin of the MAP-level may be found in structures or circumstances that are invariable among the species, such as the conditions set by the physics of the system.
In most instances, the circulatory system per se does not contribute directly to the main function of a given tissue, e.g. force development in muscle tissue. In addition there is a certain metabolic cost of maintaining a distributing system, i.e. of vessel walls and of the blood itself, increasing with the volume occupied by the system. Arguably therefore, distribution systems such as vascular networks, should occupy as little space as possible within the parenchyma. On the other hand, the distribution system must reach within a sufficiently small distance from every point in the tissue to overcome the limitations set by diffusion properties of substances necessary to sustain tissue metabolism. Different networks with vessels of different dimensions can full-fill the latter requirement however, more narrow vessels requires a larger pressure-volume work pr. volume blood delivered to the tissue. Hence, a balance must exist between not occupying to much space on one hand and not requiring too much energy for the pressure-volume work on the other hand. This balance may be central in determining the MAP.
Although blood cells are flexible, the smallest vessels, i.e. the capillaries, must have a size that allows for their passage. Given that capillaries has a certain smallest possible diameter and with capillary length and density being set, average capillary flow velocity must have a size ensuring that the diffusion field of the different species satisfies the surrounding tissues. The question is therefore: which perfusion pressure is needed to deliver blood that has a certain flow-velocity in the capillary bed? Obviously this problem does not have a unique solution since an infinity of combinations of different perfusion pressures and different network structures may give rise to a specific capillary flow-velocity. However, if the physics of the system, i.e. capillary dimensions and a "cost" of increasing the volume of the network sets constraints on the network structure, then one of the two unknowns are fixed and perfusion pressure may converge towards a specific level.
To access this problem we present a simple network model composed of a large number of individual vessels. Except for the capillaries, whose dimensions are maintained constant, every vessel in the network is allowed to adapt structurally as regards both lumen diameter and wall-thickness. It is required that each vessel adapts dynamically to a disturbance so as to regain a certain homeostatic state. Homeostasis in this regard means the effect on the vessel wall of transmural pressure and luminal flow. The basic vasomotor mechanisms sensitive to these entities are the myogenic response and the flow-dependent mechanism operating via circumferential wall stress and endothelial shear stress respectively. Whereas these mechanisms set the basic level of vascular tone, they are subject to modulation by other mechanisms such as local metabolism and vascular conducted responses. Eventually all mechanisms feed into a common activation function that determines vascular diameter both acutely (through changes in tone) and chronically (through changes in structure). Simultaneously with these processes, perfusion pressure is allowed to change freely.
On performing full-scale simulations of the model each vessel eventually settles in a homeostatic state. At this point networks with realistic structural and hemodynamic properties have emanated. Furthermore, the network perfusion pressure eventually settles at a specific value.
The present very simple model indicate that perfusion pressure may be determined by structure and diffusion properties at the lowest level of the system, i.e. the capillary bed, and that the upstream resistance network and the downstream venoular network can adapt so as to ensure a sufficient capillary perfusion while each vessel at the same time remain in homeostasis as regards wall stress and activation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA346

Microvascular network assessment in the clinic

D. De Backer

Intensive Care, Erasme University Hospital, Brussels, Belgium

Tissue perfusion assessment at bedside in critically ill patients still depends largely on measurement of global hemodynamic variables such as arterial pressure, cardiac output and mixed venous oxygen saturation (SvO2). However, alterations in distribution of regional perfusion and, even more importantly, alterations in microcirculatory perfusion often occur and impair tissue perfusion even when global perfusion is preserved.
How can we measure the microcirculation? Recently developed tools to assess the microcirculation include small hand held microscopes, such as orthogonal polarization spectral (OPS)/sidestream dark field (SDF) imaging (primarily in the sublingual region). These allow direct visualization of red blood cell flowing in the microcirculation, and hence are particularly useful to evaluate perfusion and in particular density of perfused vessels and heterogeneity in perfusion. Of note, white blood cells and platelets are hardly detected. These microscopes can be applied of tissues covered by a thin epithelial layer. In humans it was mostly used in the sublingual area. In the operating field, it can be directly applied to the heart, but great caution should be used to minimize motion artifact and to discard bloody secretions. The use of near-infrared spectroscopy (NIRS), can also be useful but it requires performance of a transient vascular occlusion test to evaluate microvascular reactivity. Hence, it is used in primarily in the thenar eminence. Measurement of tissue oxygenation with actual tools, including NIRS, without performance of vascular occlusion test is of limited interest. Indeed, this is a regional measurement of oxygen saturation but this measurement aggregates multiple vessels O2 saturation and fails to evaluate microcirculatory perfusion especially when perfusion is eterogeneous. Extensive discussion of the different techniques can be found in a recent review paper [1].
In humans, it has been shown that microcirculatory alterations occur in patients with severe sepsis [2] and in patients with severe heart failure [3]. These alterations were no related with systemic hemodynamic variables [4]. These alterations are characterized by heterogeneity of perfusion with capillaries with stop flow in close vicinity to well perfused capillaries. Different mechanisms have been implicated in the development of these alterations including loss of communication between vascular segments, impaired endothelial vasoreactivity, alterations in red and white blood cells rheology, alteration in endothelial glycocalyx, platelet aggregation and microthrombosis.
What are the consequences of theses alterations in microvascular perfusion? The presence of stop flow capillaries favours development of zones of tissue hypoxia, even though total perfusion to the organ is preserved. Heterogeneity in perfusion is a crucial problem, leading to inadequate matching of flow to metabolism. In critically ill patients, the severity of microvascular alterations are independently associated with outcome [2;3;5-7].
How can these alterations be influenced? The first point is of course to minimize the factors leading or contributing to their development. Increasing flow without recruiting the microcirculation is ineffective. The role of fluids, transfusions, inotropic agents is quite variable. The use of vasodilatory agents has been proposed but there is still insufficient evidence to support their use. In particular, due to their absence of selectivity, these can also dilate already perfused vessels and lead to a steal phenomenon. Other agents such as anticoagulant agents, vitamin C and statins may improve the microcirculation.

Compartmentation of nitric oxide synthase regulates $^{Ca2+}$ signaling in heart

Y. Zhang

Department of Physiology, Seoul National University, College of Medicine, Seoul, Republic of Korea and Yan Bian University Hospital, Yanji, China

Cardiac neuronal nitric oxide synthases (NOS1 or nNOS) has been well documented to regulate myocardial contraction and relaxation by targeting specific $^{Ca2+}$ handling proteins, protein kinase- or phosphatase-dependent phosphorylation/dephosphorylation and redox homeostasis. Specif$_{ICa}$lly, in left ventricular (LV) myocytes from healthy heart, NOS1 modulates myocardial inotropy and the amplitude of $^{Ca2+}$ transient by limiting $^{Ca2+}$ influx via attenuating L-type $^{Ca2+}$ channel activity ($_{ICa}$) through protein phosphatase 2A (PP2A)-dependent dephosphorylation of $_{ICa}$ and by increasing $^{Ca2+}$ leak following s-nitrosylation of RyR (increase subconductance of RyR). On the other hand, NOS1 facilitates myocardial lusitropy by promoting sarcoplasmic $^{Ca2+}$-ATPase activity and $^{Ca2+}$ reuptake through increasing PKA-dependent (and cGMP/PKG-independent) phospholamban phosphorylation at serine 16 (PLN-Ser^{16}) secondary to PP2A inhibition. Furthermore, NOS1 inhibits superoxide production from both XOR and NADPH oxidase. These compelling evidences show that NOS1 interacts with molecules in different subcellular compartments and exerts different effects in the heart.
Importantly, the protein expression and the activity of NOS1 are increased in hypertrophic and failing myocardium and NOS1 up-regulation is associated with cardiac protection from

oxidative stress, injury and arrhythmia. Under these conditions, NOS1 has been shown to traffic away from RyR to caveolin 3 in sarcolemma, suggesting that nNOS may target distinctive $^{Ca2+}$ handling molecules from healthy conditions under stress. So far, our understandings of the upstream or downstream mechanisms mediating NOS1 transcription and NOS1 regulation of cardiac function in the heart under stress are sparse. Recently, we have demonstrated that the pathogenic stimulator, angiotension II (Ang II) is the upstream stimulator of NOS1 protein expression and activity. Our results demonstrated that type 1, type 2 Ang II receptors and Mas receptor (in the absence of Ang 1-7) mediated Ang II stimulation of NOS1 in LV myocytes, which *in turn*, inhibited NADPH oxidase activity and facilitated LV myocyte relaxation. Unexpectedly, NOS1 up-regulation was associated with unchanged $_{ICa}$ and myocyte contraction. In addition, NOS1 increased PLN-Ser^{16} through cGMP/PKG-dependent mechanism (independent of PKA, CaMKII or peroxynitrite signaling). Similarly, NOS1 was up-regulated in cardiac myocytes from Ang II-induced hypertensive hearts, facilitated LV myocyte relaxation and decay kinetics of $^{Ca2+}$ transients (tau) and increased PLN-Ser16. Again, myocyte contraction and $_{ICa}$ were remained unaltered. Surprisingly, increased PLN-Ser16 and tau were ineffective to NOS1 inhibition; in contrast, NOS1 were shown to modulate myofilament $^{Ca2+}$ sensitivity by regulating the phosphorylation of key proteins in sarcomere.

Collectively, these results suggest that NOS1 shifts its target proteins for effective regulation of cardiac function in the myocardium under stress. This novel mechanism is important in better understanding of the endogenous cardiac protective mechanisms of NOS1 during disease progression.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Spatial coupling between pH and Ca^{2+} in the ventricular myocyte

P. Swietach[1], J. Youm[1], N. Saegusa[2], C. Leem[3], K.W. Spitzer[2] and R.D. Vaughan-Jones[1]

[1]Department of Physiology, Anatomy and Genetics, Oxford University, Oxford, UK, [2]Nora Eccles Harrison Cardiovascular Research and Training Institute, University of Utah, Salt Lake City, UT, USA and [3]Department of Physiology, University of Ulsan College of Medicine, Ulsan, Republic of Korea

Most cells are exquisitely responsive to calcium (Ca^{2+}) (1) and hydrogen (H^+) ions (i.e. pH) (2). In cardiac myocytes, Ca^{2+} ions trigger contraction and control growth and development (3), whereas H^+ ions, which are generated or consumed metabolically, are potent modulators of virtually all biological processes (4). By acting on Ca^{2+}-handling proteins directly or via other molecules, H^+ ions exert both inhibitory and excitatory effects on Ca^{2+} signaling. Due to slow diffusion and common buffering, changes in cytoplasmic $[Ca^{2+}]$ or $[H^+]$ ($[Ca^{2+}]_i$, $[H^+]_i$) can become compartmentalized, leading potentially to complex spatial Ca^{2+}/H^+ coupling.

We investigated the relationship between intracellular pH (pH_i) and diastolic or resting $[Ca^{2+}]_i$ by fluorescence-imaging of rat ventricular cardiac myocytes loaded with reporter-dyes for Ca^{2+} (Fluo3) or pH (cSNARF1). An increase in $[H^+]_i$, produced by superfusion of 80mM acetate (salt of membrane-permeant weak acid), evoked a 47±2% $[Ca^{2+}]_i$-rise, independent of sarcolemmal Ca^{2+}-influx (replacing extracellular Na^+ with N-methyl-D-glucamine and Ca^{2+} with EGTA), electrical pacing (2Hz field stimulation) or release from mitochondria (10 μM ruthenium-360), sarcoplasmic reticulum (10 μM thapsigargin or 10 mM caffeine) or acidic-stores (5 μM bafilomycin or 100 μM glycyl-L-phenylalanine 2-naphthylamide). Photolytic H^+-uncaging from the membrane-permeant donor 2-nitrobenzaldehyde also raised $[Ca^{2+}]_i$. The $[Ca^{2+}]_i$-rise evoked by H^+-uncaging or superfusion with acetate was absent in cells that were loaded with the pH-insensitive exogenous Ca^{2+}-buffer BAPTA, either as the membrane-permeant acetoxymethyl ester or as the membrane-impermeant salt via patch-pipette (confirming that the H^+-evoked $[Ca^{2+}]$-rise is cytoplasmic). Inhibition of mitochondrial respiration with FCCP (1-5 μM), rotenone (10 μM), myxothiazole (10 μM), or of glycolysis with deoxyglucose (2 mM), reduced the H^+-evoked $[Ca^{2+}]_i$-rise in a manner that correlated with the decline of [ATP] (determined by luciferase assay). H^+-uncaging into buffer-mixtures in-vitro demonstrated that Ca^{2+}-unloading from proteins, histidyl-dipeptides (HDPs; e.g. carnosine) and ATP can underlie the H^+-evoked $[Ca^{2+}]_i$-rise. Raising $[H^+]_i$ tonically at one end of a myocyte (regional exposure to 80 mM acetate using dual-microperfusion) evoked a local $[Ca^{2+}]_i$-rise in the acidic microdomain, which did not dissipate spatially but, instead, was maintained for as long as $[H^+]_i$ was compartmentalised. Activating membrane-bound acid-extruding and acid-loading transporter-proteins on either end of the cell using dual microperfusion also produced standing pH_i and $[Ca^{2+}]_i$ gradient. These results are consistent with uphill Ca^{2+}-ion transport into the acidic-zone via Ca^{2+}/H^+-exchange on diffusible HDPs and ATP molecules, energized by the spatial $[H^+]_i$-gradient. Ca^{2+}-recruitment to a localized acid-microdomain was greatly reduced during intracellular Mg^{2+}-overload (superfusion with 30 mM Mg^{2+} in the absence of Na^+ and Ca^{2+}) or by metabolic inhibition (rotenone and deoxyglucose), maneuvers that reduce the Ca^{2+}-carrying capacity of HDPs (displacement of buffer-bound Ca^{2+} by Mg^{2+}) and deplete ATP-levels. By exchanging Ca^{2+} for H^+, diffusible cytoplasmic Ca^{2+}/H^+ buffer-molecules act like local 'pumps', producing uphill Ca^{2+}-movement within cytoplasm, in response to H^+-ion gradients.

We conclude that cytoplasmic HDPs and ATP underlie spatial Ca^{2+}/H^+ coupling in the cardiac myocyte, by providing ion exchange and transport on common buffer-sites. Cytoplasmic histidyl-dipeptides and ATP thus act like a *biological 'pump' without a membrane*. Moreover, the involvement of Ca^{2+}-bound ATP confers metabolic sensitivity to the cytoplasmic H^+-Ca^{2+} interaction. Results indicate that cytoplasmic pH_i-microdomains, formed during membrane H^+- or weak acid transport will generate Ca^{2+}-microdomains. These may help to compensate for the reactive effects of H^+-ions on Ca^{2+}-dependent protein function. Given the abundance of cellular HDPs and ATP, spatial Ca^{2+}/H^+ coupling is likely to be of general importance in cell signaling.

Orchestration of signaling microdomains in heart by cytoskeleton and protein scaffolds

J.J. Saucerman, E.C. Greenwald and R. Polanowska-Grabowska

Biomedical Engineering, University Of Virginia, Charlottesville, VA, USA

There is growing evidence that subcellular compartmentation allows signaling pathways to perform multiple functions while maintaining input-output specificity. For example, cyclic AMP signaling in the heart regulates contractility, metabolism, apoptosis and hypertrophy in a receptor-specific manner. Quantitative models and experimental approaches are needed to understand precisely how subcellular compartmentation of signaling is achieved, and how such compartmentation affects specificity and other signaling properties. I will discuss two examples of how we have combined computational models and live-cell imaging to elucidate mechanisms and consequences of signaling compartmentation.

Compartmentation of cyclic AMP signaling is widely recognized to be regulated by localized degradation by phosphodiesterases. However computational models by our group and others have predicted that phosphodiesterases are not sufficient: physical barriers are also required to quantitatively explain cyclic AMP compartmentation. We have developed a new technique to directly assess the role of physical barriers in cyclic AMP compartmentation. Fluorescently labeled (and phosphodiesterase resistant) cyclic AMP was microinjected into live cardiac myocytes. By both FRAP and kymograph analysis of diffusing fluorescent cyclic AMP, we measured substantially reduced diffusion than expected from its molecular weight alone. Disrupting microtubule or especially actin cytoskeleton accelerated cyclic AMP diffusion, indicating that cytoskeletal structures help restrict cyclic AMP diffusion.

Formation of protein complexes provides another major mechanism for signaling compartmentation. A-kinase anchoring proteins (AKAPs) localize protein kinase A and other signaling proteins to discrete locations, and AKAPs have been shown to regulate the specificity of both cardiac hypertrophy and contractile signaling. While most mathematical models assume free diffusion of signaling proteins, we propose a new "scaffold state switching" model of signaling within a protein complex. Using the tethering of protein kinase C (PKC) to AKAP7α as an example, we predicted and then experimentally validated acceleration and amplification of PKC signaling by AKAP7α. Further, the model predicted that AKAP7α insulates PKC from ATP- and substrate-competitive inhibitors, but not activation-competitive inhibitors. These model predictions were validated experimentally as well. The generality of the predicted amplification, acceleration and insulation by AKAPs was examined using model sensitivity analysis.

Overall, these two examples illustrate how mathematical modeling can be integrated with live-cell imaging to determine the mechanisms and functional consequences of subcellular signaling compartmentation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Caveolae contribute to spatial control of cAMP within the cardiac cell

S. Calaghan

University of Leeds, Leeds, UK

Cyclic AMP production within the cardiac cell is highly compartmentalised allowing different receptors which increase cAMP to produce distinct cellular responses. Our recent work has shown that the organisation of signal components within microdomains of the cell membrane makes a significant contribution to spatial cAMP control [1,2]. Lipid rafts are liquid-ordered domains of the membrane enriched in cholesterol and sphingolipids. Caveolae ('little caves') are invaginated rafts defined by the presence of caveolin (Cav) and cavin proteins. Clustering of elements of particular signal cascades within a caveola promotes efficiency and fidelity of signalling, and caveolin provides additional control through its regulatory interaction with many protein partners via a 20 residue caveolin scaffolding domain (CSD). Although caveolae and non-caveolar rafts co-exist, evidence suggests that most proteins are clustered by caveolae in the cardiac cell [3].

In the adult rat ventricular myocyte, stimulation of β1- and β2-adrenoceptors (AR) and the type E prostaglandin receptor (EPR) increases total cellular cAMP (indexed using a cytosolic FRET cAMP biosensor based on Epac2). However activation of these receptors produces diverse functional responses. β1-AR stimulation increases $I_{Ca,L}$ and $[Ca^{2+}]_i$ and has pronounced positive inotropic and lusitropic effects. By contrast, β2-AR stimulation has a minimal impact on these parameters and EPR stimulation is without effect. Clearly, the cAMP signal produced by stimulation of these 3 receptors has access to different subcellular sites. The inotropic and lusitropic response to β1-AR stimulation can be directly linked with a large and sustained increase in cAMP seen specifically in regions where protein kinase A (PKA) type RII is tethered to A kinase anchoring proteins (assessed using a PKA-based sensor). Only transient changes in cAMP were recorded in this compartment following β2-AR and EPR stimulation. Disruption of caveolae with the cholesterol-depleting agent methyl-β-cyclodextrin (MBCD) enhanced PKA probe responses to β1- and β2-AR (but not EPR) stimulation but was without effect on Epac2 probe responses. Again, the change in PKA probe response with MBCD was directly correlated with functional changes: enhanced inotropic and lusitropic responses to stimulation of both β-AR subtypes were seen. As β2-AR are predominantly caveolar, β1-AR are found in both caveolar and non-caveolar fractions, whereas EPR are excluded from caveolar fractions, these data suggest that disruption of caveolae selectively promotes production of cAMP in a PKA RII domain through effects on receptors located in caveolae (i.e. all β2-AR and a subset of β1-AR). A simple explanation for this is that MBCD removes the normal inhibitory effect of Cav3 on adenylyl cyclase (AC) thereby promoting cAMP production.

Interestingly, the cAMP signal revealed by caveolar disruption has access to different sites depending on the β-AR receptor activated. With β1-AR stimulation MBCD treatment increases $I_{Ca,L}$ and hastens relaxation and $[Ca^{2+}]_i$ transient decay, consistent with targeting of both the Ca2+ channel and phospholamban (PLB) by the enhanced cAMP signal. By contrast, the nascent β2-AR cAMP signal seen following MBCD treatment only targets PLB; no increase in $I_{Ca,L}$ or phosphorylation of TnI or RyR are observed. The marked increase in phosphorylation of PLB (pPLB) evoked by β2 AR stimulation in MBCD-

treated cells is mimicked by selective disruption of Cav3 binding using a cell-permeable Cav3 CSD peptide, consistent with a caveolae-specific effect of MBCD. Although AC activity may increase if the inhibitory influence of Cav3 is removed, our data suggest that the main factor contributing to the caveolar compartmentation of β2-AR signalling is facilitation of coupling of the β2-AR with Gi which inhibits cAMP production [4]. However, this does not explain the selective control of pPLB. We believe that this can be accounted for by the fact that phosphorylation of PLB is selectively restrained by PP1 tethered along with its inhibitor I-1 to AKAP18δ [5]. The sustained (and propagating) cAMP signal seen when β2-AR-Gi coupling is severed by caveolar disruption acts as a switch to turn off PP1 by PKA-phosphorylation of I-1, thereby allowing phosphorylation of PLB to be maintained.
In summary, our work shows that compartmentation of cAMP signalling can be explained, in part, by the organisation of proteins in membrane microdomains. Cavaolae normally act to restrain the cAMP signal specifically in PKA RII domains following stimulation of caveolar β1- and β2-ARs. Given this, we predict that alterations in caveolae seen in disease (e.g. heart failure) and with treatment for disease (e.g. statins) will make a significant contribution to spatial control of cAMP and cardiac function during sympathetic stimulation.

Imaging brain activity from capillaries

S. Charpak

Paris Descartes University, Paris, France

The need for a non-invasive technique to monitor oxygen *in vivo*, in 3D and in both tissue and vessels, have stimulated more than two decades of research, based on the phosphorescent quenching method. Using two-photon phosphorescence lifetime microscopy (2PLM), we have performed depth-resolved micron-scale measurements of the oxygen partial pressure (P_{o2}) in both the neuropil and the vessels of the rodent olfactory bulb. In capillaries of glomeruli, 2PLM has also allowed simultaneous measurements of P_{o2} and blood flow, and revealed the presence of erythrocyte-associated transients (EATs), i.e. P_{o2} fluctuations associated with each individual erythrocyte. We have then investigated the extent to which EAT properties in capillaries could report local neuronal activity. We find that at rest, P_{o2} at EAT peaks overestimates the mean P_{o2} by 35 mm Hg. P_{o2} between two EAT peaks is at equilibrium with, and thus reports, P_{o2} in the neuropil. During odor stimulation, a small P_{o2} decrease is detected in capillaries prior to functional hyperaemia, demonstrating that the P_{o2} initial dip, controversial in the field of fMRI, is present at the level of capillaries. We conclude that imaging oxygen dynamics in capillaries provides a unique and non-invasive approach to finely map brain activity.

Astroglial hemichannels modulate UP and DOWN states in the olfactory bulb

L. Roux[1,2], A. Madar[1], M. Lacroix[3,4], K. Benchenane[3,4] and C. Giaume[1]

[1]Collège de France, CIRB, CNRS UMR 7241, INSERM U1050, MEMOLIFE, Université Paris 6 ED158, Paris, France, [2]Neuroscience Institute, NYU Langone Medical Center, New York, NY, USA, [3]MOBs team, Laboratory of Neurobiology, ESPCI - ParisTech, Paris, France and [4]UMR 7637, CNRS, Paris, France

While the role played by astrocytes in synaptic transmission has now largely been documented, their contribution to network activities only starts to be appreciated. A typical feature of astrocytes is their high rate of connexin expression (Cx43 and Cx30), the molecular basis for gap junctional communication and hemichannel (HC) formation. Even though connexin-formed HCs have been shown to be permeable to several neuroactive compounds, their role in physiological conditions has largely been unexplored. We thus question whether the function of Cx-based HCs in astrocytes has an impact on neuronal network behaviors in the mouse olfactory bulb (OB).
In OB acute slices, we observed that the membrane potential of mitral cells (MCs) alternates between a DOWN (hyperpolarized, silent) and an UP (depolarized, spiking) state at a slow frequency (~0.2Hz), resembling slow oscillations observed in cortical neurons during slow-wave sleep. Such alternations were inhibited by a pharmalogical blockage of glutamatergic transmission and correlated with the local field potential monitored within the corresponding glomerulus, highlighting a network effect. Interestingly, this spontaneous neuronal activity induced the opening of Cx HCs in astrocytes as shown by ethidium bromide uptake assays. We then asked whether such astroglial HC activity can in turn impact on the slow network activity, using knock-out (KO) mice for astroglial Cxs. In absence of Cx43, but not Cx30, MCs showed significant decrease in UP state amplitude compared to control. This alteration was mimicked by a blockage of Cx43 HCs, pointing out the role played by Cx43 HC function in the modulation of MC UP and DOWN states. Importantly, we found that this effect requires the activation of adenosine A1 receptors, likely via ATP release by astrocytes through Cx43 HCs. These results suggest that Cx43 HC function in astrocytes is promoted by neuronal activity, and in turn modulates neuronal network activity. Such bidirectional neuroglial interactions could play an important role in olfactory information processing.

Astrocytes control release of noradrenaline in the locus coeruleus via a novel signalling mechanism

A.G. Teschemacher[1], F. Tang[1], S. Lane[1], A. Korsak[2], A.V. Gourine[2] and S. Kasparov[1]

[1]Physiology and Pharmacology, University of Bristol, Bristol, UK and [2]Physiology, Pharmacology and Neuroscience, UCL, London, UK

Astroglia is now accepted as an active player in information processing in the central nervous system, playing a role in a variety of vital functions. Astrocytes may influence activity of adjacent neurons via a number of mechanisms, including release of signalling molecules, such as ATP, D-serine and glutamate. In addition, according to the 'astrocyte-to-neuron lactate shuttle' hypothesis, astrocytes generate L-Lactate (LL) from glucose or glycogen and deliver it to the extracellular space from where it may be taken up by neurones and consumed as preferred energy substrate (Suzuki et al., 2011).

We used optogenetics to stimulate astrocytes in rat organotypic cultured slices containing the locus coeruleus (LC), the largest group of brain noradrenergic (NAergic) neurones. Optogenetic actuators ChR2(H134R) or the rhodopsin-β2-adrenoceptor chimaera Opto-β2-AR (Airan et al., 2009) were introduced with adenoviral vectors and expressed by a transcriptionally enhanced, compact glial fibrillary acidic protein promoter (Liu et al., 2008) to ensure astrocyte-selective expression. We then measured electrophysiological responses in adjacent noradrenergic neurones by patch clamp, or monitored noradrenaline (NA) release using fast-scan cyclic voltammetry.

We found that that optogenetic activation of astrocytes leads to excitation of LC neurones. Depolarisations were suppressed by treatment with the glycogen metabolism blocker 1,4-dideoxy-1,4-imino-D-arabinitol (DAB; 500μM) or co-application of D-lactate (2 mM), but not by treatment with the monocarboxylate transporter blocker 4-CIN (100uM). This suggests that the excitation may be triggered by LL, released by activated astrocytes, and acting on a substrate located on the extracellular side of the cell membrane of LC neurones. Exogenously applied LL (0.2 – 20 mM) was also excitatory to LC neurones. These effects were not due to pH or caloric effects of LL as intracellular LL (2 mM), or extracellular pyruvate were ineffective.

Using fast scan cyclic voltammetry, we found powerful NA release in response to optogenetic activation of astrocytes or application of LL. These responses were also sensitive to DAB and D-lactate.

Microinjection of LL into the LC of urethane (i.p.) anaesthetised rats *in vivo* caused an increase in arterial blood pressure and changes in EEG qualitatively similar to those of L-glutamate, an established excitatory transmitter.

Together, these effects of LL may not be explained by its value as an energy substrate for LC neurons but are consistent with its role as an inter-cellular signalling molecule operating between astrocytes and NAergic neurones. Moreover, they imply an existence of as yet unknown receptor for this new "glio-transmitter".

Brain and mind reading

G. Rees

Institute of Cognitive Neuroscience, UCL, London, UK

Everything we know about the world comes to us through our brain. Yet for each of us our own conscious mental world of thoughts and feelings is isolated and private. Despite several centuries of research on the brain, communication through language or gesture remains the only way we can discover the conscious thoughts and experiences of others. But if thoughts and feelings arise from patterns of neural activity in the brain, then it should be possible to directly decode such conscious experiences from brain activity alone. Recent advances in brain imaging technology raise just such a possibility, by showing that it is possible to accurately decode a person's conscious experience based only on non-invasive measurements of their brain activity. Moreover, recent research demonstrates that there is substantial variability in how different people experience the same physical environment and that this can be indexed by structural and functional imaging of the human brain. Such 'brain reading' abilities may transform our understanding of the brain and provide important new medical insights, but also raise important ethical issues concerning the privacy of personal thought and behavioral predispositions.

I know what you're thinking: brain imaging and mental privacy. Eds Richmond S, Rees G & Edwards SJL. Oxford University Press 2012

The Brain Imaging Dialogue: navigating the politics of science and technology

O. Escobar

School of Social and Political Sciences, University of Edinburgh, Edinburgh, UK and Public Policy Network, Academy of Government (University of Edinburgh), Edinburgh, UK

This presentation addresses a fundamental issue at stake in this symposium: Notwithstanding whether brain imaging is an ethical time bomb or not, who should deal with it in policy terms and how? Firstly, I will briefly outline lessons learned from the Brain Imaging Dialogue process that took place in Scotland during 2010, and which brought together a range of participants including scientists, technicians, health prac-

titioners, legal experts, social scientists, policy makers and members of the public to discuss the social and policy implications of current and future non-medical uses of brain imaging.
Secondly, I will argue that, in a democracy, the appropriate way to deal with an issue of this nature is through substantial public engagement. In other words, it is no longer enough that expert and policy elites shape the way we govern an array of technologies that bring with them such fundamental ethical, social and political challenges. Insofar we are talking about values and good practice, considered judgement by citizens must be at the heart of any process that seeks to legitimately address those challenges in policy terms.
Accordingly, I will conclude by proposing the use of democratic innovations such as deliberative 'mini-publics' (e.g. consensus conferences, citizen juries, planning cells, citizen assemblies, deliberative polls) in order to address this issue and make informed policy through meaningful public engagement.

I would like to thank the organisers of the Brain Imaging Dialogue programme "What are you thinking? Who has the right to know? Brain imaging and its impact in society", which took place at the Scottish Universities Insight Institute in Glasgow during 2010. I am deeply indebted to them for letting me be part of that process and supporting my research.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA356

The business of brain imaging – a commercial perspective

G. Calvert

Marketing, Nanyang Technological University, Singapore, Singapore

Traditional market research relies on measuring consumers' explicit responses via questionnaires, surveys or focus groups in order to predict how brands, new products or messages will fare in the marketplace. However, with approximately 80% of all new products failing within their first year to market despite millions of dollars spent on explicit pre-testing, companies have been looking into alternative ways to find out with greater accuracy what consumers really want. Enter the rapidly expanding field of "neuromarketing" – the application of state-of-the-art brain imaging tools and methods from psychology and neuroscience to understand consumer behaviour at a much deeper level than has been possible previously.
Neuroscientists now agree that a great deal of human behaviour is driven by brain processes that operate below the level of conscious awareness and that emotions rather than rational deliberations are, more often than not, determinants of choices. So market research that relies solely on explicit conscious responses offers only a partial picture of the multitude of brain processes (predominantly subconscious) that shape consumer behaviour. Over the past two decades, neuroscientific methods such as functional MRI and EEG have been used to study and define these explicit and implicit neural mechanisms. Companies too have conducted a substantial amount of research using the full gamut of neuroscientific approaches to understand, and ultimately predict, consumer behaviour with far more accuracy than has been permitted by reliance on spoken feedback. Areas of specific commercial interest include finding out the extent to which marketing messages or campaigns are encoded into long-term memory, whether key frames within a television commercial have been absorbed and whether changing certain parameters of a new product alters the extent to which it stimulates the brain's reward areas. The range of human emotions that manufacturers are now able to measure is considerable: trust, anticipation of price, brand loyalty and empathy are just a few.
For years, manufacturers have sought a closer alliance with their customers, recognising that including them in the design and manufacturing process not only delivers superior products but also enhances the customer experience and builds loyalty to the brand. And while not a panacea – the human brain is an extraordinarily complicated organ and neuroscientists have some way to go before they understand it completely – there is little doubt that neuromarketing offers manufacturers a more objective and scientific framework for the study of consumer behaviour. But should consumers be concerned that the ability to see inside our heads and capture our subconscious responses will allow marketers to manipulate us into making purchasing decisions that we otherwise would not?
In this talk, I will examine some of the issues that are at the forefront of the neuromarketing debate including issues of infringement of privacy, scientific integrity and ethical standards. Such factors must be considered in the light of the substantial benefits to global industry and consumers (less wastage and improved product satisfaction through more accurate understanding of what consumers really want) that can be offered by applied neuroscience.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA357

The promises and perils of brain imaging technology: an ethical perspective

L.Y. Cabrera

Inst. Biomedical Ethics, University of Basel, Basel, Switzerland

One area of incredible advances and promises within neurotechnology has been brain imaging technologies (BIT). But great promises often come along with great perils. In addition, given that BIT is not confined any more to the clinical setting the different ethical issues it can bring to the fore go beyond those that are regularly discussed in the medical context. For instance, who should see or have access to our brain image? Should neuroimages be used as evidence in court? Or for commercial issues? Here I will explore from a neuroethics perspective some of the promises and perils surrounding the uses of BIT outside the medical and research arenas.
BITs are generally seen as technologies to monitor brain function. Among BIT one of the most portrayed in the media and public discourse is functional Magnetic Resonance Imaging (fMRI), but there are other imaging technologies, such as Positron emission Tomography (PET) and electroencephalography EEG. BIT has unique capabilities inasmuch as it can help us to understand the brain in detail and depth that previous technologies and methods have not enabled us to achieve before. It can also help us to understand how the brain develops, changes and wires itself, which in turn can shed light into our understanding of human behavior and cognition. So among the promises of BIT we found claims related to it helping us to better monitor and diagnose neuro-related diseases and conditions, which could have a positive impact for society. However, we should bear in mind that at present BIT is

far from being perfect, and its reliability is often questioned, being charged with issues related to overinference, neuroaesthetics, confirmation bias, and trait state confusion (Farah, 2010, Wolpe et al, 2005).

There is another source of concern, namely the way neuroimaging results are interpreted. Some people have seen the potential of BITs to tell us something about mental states which can then be used for: neuromarketing, lie detection (brain reading), and assessment of potential dangerousness. Others have seen it as the analogous to genotyping, in which through our brainotype we will be able to measures, for instance how personality traits are reflected in the brain's functional architecture and as such determine the kind of persons we are or how different brain areas at work can tell us about morally relevant intuitions and those that are not (Levy, 2011). However, it is questionable the ability of brain imaging to provide an objective interpretation of complex social behavior (Phelps and Thomas, 2003), such as whether someone is lying (Wolpe and Foster, 2005), likely to show dangerous behavior or about our morality (Cabrera, 2011). It is one thing to use BIT to predict the likelihood of someone developing a certain neurological condition and another thing to say that we can use BIT to predict dangerousness. Imaging technologies can tell us that certain mental activity correlates with activity in certain brain region, but not whether the activity is actually the result the mental activity itself. Now, even if we ever developed a BIT with which we feel comfortable to use for assessing whether someone has committed or not a crime, or whether that someone shows a 'dangerous brain' and as such it is unsuitable for release, it will not make much sense to use it for such purposes unless we already have a program in place to deal with the positive cases we might encounter.

We have to remain cautious in the ways we use neuroimaging technologies but also in the way we interpret neuroimages. The new understandings that BIT promise to give us can certainly help us to capture the dynamic and complex ways of our mental life, including our intuitions, beliefs, desires as they tell us about their neural/psychological bases and the way they are influenced by reasoning, emotion, and social influences; but these new understandings could also reduce complex human behaviors to just certain brain activities while stigmatizing other important resources and elements of our mental processes (Cabrera, 2011). As Martha Farah (2010) has put it "some of the most profound ethical challenges from neuroscience come not from new technologies but from new understandings". Thus, if we want to ensure that these technologies are used for the benefit of our society, then we have to start questioning ourselves about the practical value of neuroscientific knowledge and how we should best realize it.

SA358

Society meets neuroimaging – likely tensions

H. Greely

Stanford University, Stanford, CA, USA

As neuroimaging and neuroscience tell us more about how the human brain works, this knowledge inevitably will have both medical and non-medical implications for society. Many of those implications will be based on accurate understandings of the new science; others will stem from misunderstandings – and some of them the result of willful exaggeration. Whether the science is accurate or not, the social effects may be substantial.

This talk will survey six areas where new neuroscience results are likely to affect society beyond solely medical consequences: prediction, mind-reading, responsibility, treatment, enhancement, and culture. Neuroimaging will improve our ability to predict future mental health, neurological conditions, and behavior. It will allow us, in some circumstances, to do make better inferences about what a person's mental states, whether that involves deception, pain, or more general communication. Responsibility – criminal, civil, and moral – is not likely to be revolutionized by neuroimaging, but neuroimaging will make its assignment, in at least some cases, more difficult. Funding for neuroimaging comes largely from hopes of finding prophylaxis, treatment, or even cures for mental or neurological illnesses, but improved understanding of brain processes may allow "treatment" for non-disease behaviors, such as criminal activity, which would raise its own set of ethical questions. Neuroscience, guided by neuroimaging, may also allow not just the ill but also the healthy to enhance their cognitive abilities. And, finally, neuroimaging may (but, I suspect, probably will not) have broader cultural consequences by affecting people's understanding of free will.

In each of these cases, many "breakthroughs" will be claimed, but few will actually occur. We need to maintain, and educate the public to, an appropriate skepticism about whether these breakthroughs really do work – and, if they work, how well. At the same, we should benefit from considering just how our societies will be affected by real progress in understanding the workings of human brains.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Molecular insights into the regulation of T cell signalling

K. Gaus

Centre for Vascular Research, University of New South Wales, Sydney, NSW, Australia and Australian Centre for Nanomedicine, University of New South Wales, Sydney, NSW, Australia

T cell activation begins with the formation of signalling complexes at the cell surface involving the T cell antigen receptor (TCR), the Src family kinase Lck and the adaptor protein, linker for activation of T cells (LAT). How early TCR signalling events are regulated to prevent inopportune signalling in resting T cells but efficient activation upon receptor ligation is poorly understood. We have established localization microscopy to determine how TCR engagement reorganizes signalling proteins on the molecular scale. Imaging single molecules in intact

cells has provided new insights into the mechanisms of Lck clustering (Rossy et al. Nat Immunol 2013) and LAT recruitment (Williamson et al. Nat Immunol 2011) upon TCR activation. We are now extending this work to elucidate how the membrane environment affects protein interactions (Owen et al. Nat Commun 2012) to better understand the molecular principles of TCR signalling regulation.

Nano-resolution fluorescence electron microscopy

S. Watanabe and E.M. Jorgensen

Biology, University of Utah, Salt Lake City, UT, USA

To fully characterize the biology of a cell, we must know where proteins are located relative to sub-cellular structures. A fluorescence tagging approach is a very robust way to localize proteins at a sub-cellular level, but the lack of cellular context in fluorescence images and the resolution of fluorescence microscopy limits the ability to localize proteins to sub-cellular structures[1]. On the other hand, immuno-electron microscopy (immuno-EM) has high resolution, but it is limited by sample preparation and availability of antibodies[1]. The strengths of fluorescence microscopy (all proteins can potentially be tagged with fluorescent proteins) and immuno-EM (resolution of sub-cellular structures) are complementary, and thus many correlative fluorescence and electron microscopy techniques have been developed. However the precision of protein localization is limited with the currently available methods.

In the last few years, new light-based microscopy techniques have been developed with almost one hundred-fold better resolution than conventional microscopes. Photo-activated localization microscopy (or PALM)[2] is one example. With this approach, individual fluorescent proteins can be localized with 10 nm resolution. The resolution of the image is comparable to that of an image acquired with electron microscopy. However, the localization of proteins relative to the sub-cellular structures is limited despite the improvement in resolution. To add subcellular context, we developed a method to preserve fluorescence in the sample embedded in plastic for electron microscopy while preserving the cellular morphology[1]. We performed super-resolution imaging on thin sections of tissues and correlated the signals to the subcellular structures revealed by electron microscopy. Using this method, we localized histones, TOM-20, and liprin to the expected organelles: the nucleus, mitochondrial membrane, and dense projection, respectively[1]. Nano-resolution fluorescence electron microscopy (nano-fEM) can be readily used to reveal the location of proteins within a cell.

Seeing the forest, tree by tree - Single molecule superresolution microscopy of multiprotein complexes

H. Ewers

UZH | ETH Zurich, Zurich, Switzerland

Single molecule localization-based superresolution microscopy methods such as PALM or STORM, have been breakthrough techniques of the last years. Until now however, they require special fluorescent proteins to be cloned or high-affinity antibodies to be generated for specific labeling. On the other hand, many laboratories will have most of their constructs in GFP form and entire genomes are available as functional GFP-fusion proteins.

Here, we report a method that makes all these constructs available for superresolution microscopy by targeting GFP with tiny, high-affinity antibodies coupled to blinking dyes. It thus combines the molecular specificity of genetic tagging with the high photon yield of organic dyes and minimal linkage error. Direct STORM on microtubules labeled with our novel antibodies showed that indeed the linkage error was minimal, whereas the large size of standard antibodies resulted in an additional error of >10 nm in immunolabeling. The brightness of our labels enabled us to perform rapid time-lapse dSTORM and sptPALM on living neurons expressing the outer membrane protein GPI-GFP. Three-dimensional dSTORM on microtubules using the biplane approach allowed us to distinguish overlapping microtubules with an axial separation of ~100 nm. Using a budding yeast GFP-tag genomic library we could readily image several GFPtagged proteins targeted to specific intracellular locations.

In summary, targeting of GFP-labeled constructs with tiny antibodies provides fast and simple access to superresolution microscopy of virtually any known protein in cells. Since for several organisms the entire genome is available as GFP-tagged constructs, all these proteins are immediately accessible without the requirement for cloning or the generation of antibodies. Finally, due to a simple one-step labeling protocol, our technique opens the door to highthroughput localization analysis of entire genomes at the nanoscopic level in cells.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA362

High-speed hyperspectral nanoscopy for studying dynamic protein interactions below the diffraction limit

K. Lidke

University of New Mexico, New Mexico, NM, USA

Many cellular signaling processes are initiated by dimerization or oligomerization of membrane proteins. However, since the spatial scale of these interactions is below the diffraction limit of the light microscope, the dynamics of these interactions have been difficult to study on living cells. We have developed

a novel high-speed hyperspectral microscope (HSM) to perform single particle tracking of up to 8 spectrally distinct species of quantum dots (QDs) at 30 frames per second. The distinct emission spectra of the QDs allows localization with ~ 10 nm precision even when the probes are clustered at spatial scales below the diffraction limit. The capabilities of the HSM are demonstrated by application of multi-color single particle tracking to observe membrane protein behavior, including: 1) resolving antigen induced aggregation of the high affinity IgE receptor, FcεR1 ; 2) dynamic formation and dissociation of Epidermal Growth Factor Receptor dimers; 3) four color QD tracking while simultaneously visualizing GFP-actin; and 4) high-density tracking for fast viscosity mapping of the cell membrane.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Conformational changes during the CLC transport cycle

A. Accardi, D. Basilio, K. Noack and A. Picollo

Anesthesiology, Weill Cornell Medical College, New York, NY, USA

The CLC proteins catalyze transport of chloride ions (Cl-) through cellular membranes in muscle, kidney, bone, and neurons. While some CLCs are ion channels others are H+-coupled secondary active transporters mediating the stoichiometric exchange of 2 Cl- for 1 H+. The exchange mechanism of the CLCs is unclear. Extensive structural and functional work suggests that the only conformational change taking place during transport is the movement of a conserved glutamate side chain in and out of the Cl- permeation pathway. However, other indirect lines of evidence suggest that regions distal to the Cl- pathway might also be involved in transport.
To test whether transport entails only local or also global rearrangements we used the crystal structure of CLC-ec1, a prokaryotic CLC homologue, to introduce crosslinks at the contact points of helices J, O, P and Q. These helices do not line the Cl- or H+ pathways. We hypothesized that if exchange involves movement of these helices then these constraints should inhibit transport. In a cys-less background we introduced pairs of cysteines at different locations in this 4-helix bundle and used Hg2+ to crosslink them. All unreacted proteins mediated Cl-/H+ exchange at rates comparable to that of the WT. Reaction with Hg2+ results in a striking pattern: constraining residues facing the extracellular side has no effect, while targeting pairs towards the intracellular side induces progressively a more drastic reduction of activity. Finally, constraints placed close to the intracellular side results in inactive transporters. This reduction is not due to a Hg2+-induced distortion of the Cl- pathway, as the structure of the "locked-shut" protein is virtually identical to that of WT CLC-ec1. Removal of either gate removes the inhibitory effect of the crosslinks, suggesting that this conformational change is part of the allosteric coupling of the two gates rather than directly control the movement of a single gate. In conclusion, our results demonstrate that the CLC exchange cycle entails a conformational rearrangement of helices outside of the Cl- transport pathway that control the coupling between the two gates.

Na+/H+ antiporters finely tune intracellular concentrations of salt and pH by rapidly exchanging sodium ions with protons across the cell membrane. In humans these integral membrane proteins play an important role in physiology and their dysfunction is associated with a number of different diseases, eg, postischemic myocardial arrhythmias, cancer, heart disease and hypertension, the latter a major disorder affecting 1 in 4 adults in the United States. Here, I will discuss new structural insights into the mechanics of Na+/H+ antiport that has enabled us to have a better understanding of how they function at the atomic level.

Dance lessons for proteins: the dynamics of the glutamate transporter homologue

O. Boudker

Physioogy and Biophysics, Weill Cornell Medical College, New York, NY, USA

Glutamate transporters are integral membrane proteins that catalyze neurotransmitter uptake from the synaptic cleft into the cytoplasm of glial cells and neurons. To pump their substrates against steep concentration gradients, they utilize the energy stored in the form of electro-chemical gradients of ions, primarily sodium. Their mechanism involves transitions between extracellular- (outward-) and intracellular- (inward-) facing conformations, whereby substrate binding sites become accessible to the opposite sides of the membrane. Our crystallographic studies on a bacterial homologue of glutamate transporters suggest that this process entails trans-membrane movements of three discrete transport domains within a trimeric scaffold. Using single-molecule fluorescence resonance

energy transfer imaging, we have directly observed large-scale transport domain movements. We find that individual transport domains alternate between periods of quiescence and periods of rapid transitions, reminiscent of bursting patterns first recorded in single ion channels using patch-clamp methods. We suggest that the switch to the dynamic mode in glutamate transporters is due to separation of the transport domain from the trimeric scaffold, which precedes domain movements across the bilayer. This spontaneous dislodging of the substrate-loaded transport domain is approximately 100-fold slower than subsequent trans-membrane movements and may be rate determining in the transport cycle. In addition, by means of X-ray crystallography, we have uncovered smaller local conformational transitions associated with substrate and ion binding in the outward- and inward-facing states of these transporters.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Structural physiology of PepT1, the mammalian proton coupled peptide transporter

S. Newstead

Biochemistry, University of Oxford, Oxford, UK

The mammalian peptide transporter, PepT1, is a member of the Proton-coupled Oligopeptide Transporter (POT) superfamily of integral membrane proteins. The POT family function by coupling the bulk uptake of short chain peptides to the inwardly directed proton motive force present across the plasma membrane in eukaryotes and inner membrane of prokaryotes. POT family of transporters range in size from ~45 – 75 kDa and contain either 12 or 14 transmembrane helices. The smaller members of the family, which are mostly found in prokaryotes, consist almost entirely as a hydrophobic bundle of helices that reside within the membrane. The larger members of the family are mammalian in origin and whilst still maintaining the same conserved transmembrane core of 12 helices, have an additional polar domain that sits on the outside of the membrane.

Substantial progress has recently been made in determining the crystal structures of the bacterial members of the POT family, in particular understanding how they bind and transport peptides across the membrane. However, the role of the extra cellular domain, found only in PepT1 and PepT2, still remains unresolved. We have recently determined the crystal structure for this domain from PepT1 at 2.2 Å enabling the construction of a hybrid model of the mammalian PepT1 transporter. Combined with in vivo functional data, a role for this domain in transport is proposed, revealing intriguing mechanistic insights into the difference between the bacterial and mammalian POT family transporters with important implications for understanding peptide transport in mammalian cells.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

From crystallographic snapshots towards a mechanism for secondary transport

C.M. Ziegler

Structural Biology, MPI, Frankfurt, Hessen, Germany

The molecular understanding of secondary transport, in particular how transport activity is regulated, is one of the cutting-edge questions in biological science (1). A number of secondary transporters show regulation of transport activity, which plays an important role in nearly all stress-induced cellular responses. Transport activity can be regulated in response to various external stimuli, which often are difficult to identify. Therefore, only a few regulated transporters are described to date; one of the best characterized amongst them is the Na+-coupled betaine symporter BetP from Corynebacterium glutamicum (2). In the last five years several atomic structures of trimeric BetP were solved in different conformational states and under active and inactive conditions (3). First insights into a molecular mechanism of regulated transport in BetP were obtained by the combination of X-ray and electron crystallography data, functional measurements, spectroscopy and bioinformatics. Thereby, the transport cycle of BetP was described in molecular detail. The key towards crystallizing different conformational state was found in a combination of rational mutagenesis of residues involved in substrate-coupling and purification methods that consider strongly the stabilizing effects of lipids.

Time to translate? Overview of myometrial contractility

S. Wray

University of Liverpool, Liverpool, UK

The focus of my presentation will be to review our understanding of myometrial contractility, how it is brought about and controlled, to highlight emerging topics of interest, and ask if we are getting closer to having new drugs to help prevent preterm or slow labours.

I will focus on recent insights into the role of the sarcoplasmic reticulum in the myometrium to illustrate how we have to study the myometrium, not other smooth muscles or cell lines, if we are to understand the uterus. I will then describe what insights may be gained from studying different patient groups, e.g. women who are obese or diabetic, pregnant with twins or going beyond their due dates. Do we now have the tools to understand the impact of these conditions on the underlying myometrial physiology? What contributions can modelling,

medicinal plants and studies of extracellular matrix and electrophysiology, make? How can we make all of this synergise so that we can bear down on being able to translate from the basic science to women in labour?

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA369

From genome-wide screens to computational modelling: finding novel targets to manipulate uterine function

A. Blanks

University of Warwick, Coventry, UK

Clinical conditions commonly associated with abnormal uterine activity are preterm labour (PTL), dysfunctional labour and post partum haemorrhage (PPH). Preterm birth is the biggest cause of neonatal mortality and morbidity. Dysfunctional labour leads to operative vaginal and abdominal delivery with its inherent maternal risks, and PPH is a major global cause of maternal morbidity and mortality accounting for around 25% of deaths in postpartum mothers in developing nations. PTL, PPH and dysfunctional labour have complex, multi-factorial aetiologies and it is unrealistic to assume that all cases will be treated by a single approach. None-the-less a greater understanding of the underlying principles of uterine contractions offers the prospect of discovering novel therapeutics for these disorders. We have established a research programme combining molecular biology, computational modeling, in vitro and in vivo physiology, and drug discovery to increase basic understanding and discover new treatments. In this presentation I shall argue that such an approach has enormous potential by using our discovery of a novel inwardly rectifying potassium channel as an exemplar.

To identify novel targets we started by using laser capture micro dissection to isolate mRNA from pure myometrial (MSMC) and vascular smooth muscle cells (VSMC) present in uterine samples taken at cesarean section. mRNA was then amplified and sequenced by RNAseq. Gene lists of all expressed ionic conductances were constructed and analysed for significant differences between MSMC and VSMC. Identified candidates were then subjected to a 'virtual' screen by computationally modeling the effect of changing channel densities/activity based on known biophysics (Aslanidi et al. 2011). One candidate, Kir7.1 was taken forward as a potential modifier of resting membrane potential and uterine excitability during gestation. qRT-PCR and western blot analysis demonstrated that Kir7.1 expression is regulated at the mRNA and protein level during gestation in mouse and human. Knockdown of Kir7.1 protein, in vitro, by lentiviral miRNA resulted in profoundly increased contractions when compared to scrambled control. Over expression of hKir7.1 resulted in inhibition of phasic contractions. Microelectrode recordings of phasic contractions in knockdown and overexpressing strips demonstrated that the observed phenotypes were mediated by a change in membrane potential. In vivo, mice injected with lentiviral miRNA demonstrated significantly increased intrauterine pressure and preterm delivery when compared to scrambled control. To explore potential therapeutic avenues at this protein target we tested the effect of the novel Kir7.1/ROMK inhibitor VU590 and VU590 (Lewis et al. 2009) like derivatives on whole cell current under voltage clamp conditions combined with current clamp recordings of in vitro contracting myometrial strips. VU590 dose dependently inhibits a Kir7.1 like current in native mouse and human MSMC, whilst addition of VU590 to contracting myometrial strips leads to rapid depolarization of resting membrane potential followed by long-lasting tonic contractions that are reversible on washout. To test whether physiological activity was specific to Kir7.1 we manufactured chemical derivatives that lost Kir7.1 activity but retained ROMK activity. These derivatives failed to affect contractions or membrane potential.

I shall conclude that genomic screening of laser-dissected tissues, taken under different physiological conditions, and combined with RNAseq is an effective means of surveying mRNA profiles. Such profiles, when combined with accurate biophysical information and computational models can lead to a rapid, predictive, focusing down on potential targets with desirable physiological phenotypes. Once identified, in vitro knockdown of targets using lentiviral delivery vectors provides an excellent first means to assess whether subsequent investment of time and resources in a drug discovery programme is worthwhile.

The importance of the smooth muscle cytoskeleton for preterm labor

K. Morgan

Boston University, Boston, MA, USA

Myometrial stretch and increases in wall tension have been implicated clinically in the initiation of labor and the etiology of preterm labor. We have taken a biomechanical and biochemical approach, using human tissues and rodent models to investigate the molecular mechanisms involved. Together with our collaborators, we have found, firstly, that the intracellular Ca requirement for activation of the contractile filaments increases during gestation. The decreased Ca sensitivity correlates with an increase in the expression of caldesmon, an actin binding protein and inhibitor of myosin activation, during pregnancy. In late pregnancy we observed an increase in ERK-mediated caldesmon phosphorylation, which appears to reverse this inhibitory effect during labor.

Force generated by the myometrial contractile filaments is communicated across the plasmalemma and to the uterine wall through the focal adhesions. Using phosphotyrosine screening and mass spectrometry of stretched myometrial samples, we identified 3 stretch-activated focal adhesion proteins, FAK, p130Cas, and alpha actinin. FAK-Y397, which signals integrin engagement, is constitutively phosphorylated in term human myometrium whereas FAK-Y925, which signals downstream ERK activation, is phosphorylated during stretch. This Src mediated signaling appears to provide a tunable tension sensor in the myometrial cell.

We have recently identified smooth muscle Archvillin (SmAV) as a new ERK scaffolding protein. A newly produced SmAV-

specific antibody demonstrates gestation-specific increases in SmAV protein levels and stretch-specific increases in SmAV association with focal adhesion proteins. Thus, whereas increases in caldesmon levels suppress human myometrium contractility during early pregnancy, stretch-dependent focal adhesion signaling, and ERK activation contribute to subsequent myometrial activation.

In parallel, biophysical measurements of smooth muscle compliance at both the cellular and tissue levels suggest that decreases in cellular compliance due to changing interactions of the actin cytoskeleton with the focal adhesions may also promote increases in uterine wall tension. Thus these results, taken together, suggest that focal adhesion proteins and their interaction with the cytoskeleton may present a new mode of regulation of uterine contractility.

Finding new agent and mechanisms in medicinal plants

S. Kupittayanant, P. Munglue, W. Lijuan, W. Proprom and N. Buddhakala

Physiology, Suranaree University of Technology, Muang, Nakhon Ratchasima, Thailand

Since ancient times medicinal plants have had an important place in preventing and treating disease. Many conventional drugs originate from plant sources, including aspirin (from willow bark), the heart drug digoxin (foxglove), and morphine (opium poppy). Scientific and modern pharmaceutical interest in medicinal plants is largely due to the need for new, safe drugs, but they remain important to many people in the developing world who do not have access to modern medicines. Several medicinal plants have been used for uterine proposes in the developing world (Gruber & O'Brien, 2011). However, the mechanisms of action of such the plants have never been elucidated. The aims of the studies in my laboratory are therefore to investigate the effects of some medicinal plants on myometrial physiology. Plant extracts were prepared from botanical sources, standardized and validated. Phytochemical screening of the crude extracts was analysed using gas chromatography–mass spectrometry. All separated compounds were identified from the recorded mass spectra by comparison with the mass spectra from the NIST and Wiley libraries. Animal cares, environmental conditions, and uses followed the guidelines of Laboratory Animal Resources and the procedures of the experiment were approved by the Institutional Animal Care and Use Committee. Rats were humanly killed. The uteri were removed and the strips of longitudinal myometrium isolated. Isometric force was measured in organ baths and vehicle and time controls were always performed. The effects of plant extracts on spontaneous and agonist-induced contraction in the uterus were investigated, and the dose response range determined. Using a pharmacological approach, the parts of the myometrial excitation contraction pathway which were affected by the extracts, were dissected. This approach provided a good amount of mechanistic information. The results showed that some of the plant extracts are potent inhibitors (Buddhakala et al, 2008; Munglue et al, 2012) whereas others are potent stimulators (Promprom et al, 2010; Lijuan et al, 2011) for the uterus. The parts in the pathways affected were extract specific and reveal many therapeutic targets, including calcium entry and sarcoplasmic reticulum release, and stimulating the NO-cyclic guanosine monophosphate relaxant pathway. Taken together, these data will give us a better understanding of how medicinal plants work on the uterus and the results of these findings can be applied in other areas of smooth muscle physiology, as well as pharmacy and medicine.

A tale of two channels-Kv7 and ERG in myometrial regulation

I.A. Greenwood

St George's, London, UK

Regulation of smooth muscle contractility is crucial aspect of uterine physiology. This is highlighted by the developmental switch that the myometrium undergoes as gestation progresses into labour. However, little is known about the molecular mechanisms that govern the change in contractile phenotype and how these mechanisms are affected in pathological scenarios. Potassium channels are integral to the control of myometrial contraction and various types of potassium channel have been identified in rodent and human myometrial smooth muscle. Our collaborative work has focussed upon the expression and functional impact of two types of voltage-gated potassium channels previously associated with neuronal and

cardiac excitability namely KCNQ- and ether-a-go-go (KCNH) genes. This talk will be give an overview of our work on these channels showing the expression of different KCNQ and KCNH isoforms in uterus from non-pregnant and pregnant animals as well as human tissues. It will also highlight the different impact of these potassium channels in myometrial contractility with ERG channels losing functional impact as gestation develops whereas KCNQ channels remain a robust and therapeutically viable target through-out pregnancy. These data have provided mechanistic insight into uterine physiology and provide new possible targets for therapeutic intervention.

Work in Dr Greenwood's laboratory is supported by the BBSRC, Action Medical Research and the British Heart Foundation with further support from NeuroSearch A/S

The role of miRNAs in cardiovascular ageing

R. Boon

Institute for Cardiovascular Regeneration, Goethe University, Frankfurt, Germany

Aging is the major risk factor for developing cardiovascular complications like endothelial dysfunction, aneurysm formation, acute myocardial infarction and heart failure. The mechanisms involved in cardiovascular aging are poorly understood, but microRNAs (miRNAs) have emerged as key biological regulators. We have identified that age-induced miR-29 has a causal role in aneurysm formation by regulating the expression of extracellular matrix proteins in the aorta. Furthermore, we recently described the crucial role for miR-34a in cardiac aging, which regulates cardiomyocyte apoptosis and telomere length by targeting the protein phosphatase nuclear targeting subunit PNUTS. Current studies in the laboratory focus on determining the role of miRNAs, their targets and their transcriptional regulators in aging of the endothelium and how these affect organ homeostasis and cellular metabolism.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA374

The role of miRNA in vascular remodeling

A. Baker

Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, UK

MicroRNAs (miRNAs) are short non-coding RNAs, which post-transcriptionally regulate gene expression. miRNAs are important in governing cell differentiation, development and disease. Our work spans the role of miRNA in the development of vascular pathologies associated with remodeling and with the vascular regenerative strategies in ischaemic conditions. We have focused on miRNA in the development of pulmonary arterial hypertension and vein graft disease. In consideration of the role played by miRNAs in cell proliferation and vascular remodeling, we evaluated the involvement of the smooth muscle cell-associated miRNAs miR-143 and miR-145 in the development of PAH, as well as the role of miRNA-21 which is more widely expressed. Significant dysregulation of these miRNAs in PAH and VG disease has been observed in animal models and in pathological samples and manipulation has been shown to the beneficial in prevention of pathological remodelling. Manipulation of miR-21 and miR-145 may therefore represent a novel strategy to prevent the development of these pathologies that have substantial unmet clinical need. Strategies to efficiently delivery these therapeutics to the vessel wall will also be discussed.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA375

microRNAs, transforming growth factor beta-1 and tissue fibrosis

R.H. Jenkins

Institute of Molecular and Experimental Medicine and Central Biotechnology Services, School of Medicine, Cardiff University, Cardiff, UK

microRNAs are small, endogenous, post-transcriptional regulators of gene expression. A single microRNA may potentially regulate several hundred protein-coding genes, and recent estimates suggest approximately 60% of human protein-coding genes are regulated by microRNAs. Changes in microRNA expression patterns are linked to profound effects on cellular phenotype and microRNAs have an emerging role in diverse physiological and pathological processes. This presentation will describe the regulation of microRNA expression by Transforming Growth Factor Beta-1, a key cytokine with pivotal roles in cellular proliferation, differentiation, motility and adhesion. Consistent with these roles, Transforming Growth Factor Beta-1 expression is a frequent observation in fibrosis-driven pathology. In this context, I will discuss data from our laboratory focusing on the role of miR-192 in the pathogenesis of acute and chronic kidney disease.

Role of miRNAs in mitochondria and genetic disease

A. Henrion-Caude

Imagine Institute, Inserm U781, Paris, France

MicroRNAs (miRs) are most often depicted as fine-tuners of gene expression, and more occasionally as genetic switches. Still few examples delineate their contributions as phenotypic modulators. We reasoned that browsing their contribution to genetic disease could provide a framework for understanding some of the requirements to devise miRNA-based therapy strategies. Here we will browse through what appeared as a mitochondrial view of miRs. We will provide examples showing that miRs may be crucial in the regulation of mitochondrial components, such as in the case of Friedreich ataxia. Conversely, we will present the rationale that supports their involvement within the mitochondrion.

We thank the AFAF for their financial support.

Type 1 angiotensin receptors in the kidney and the control of blood pressure

S.B. Gurley, J. Stegbauer, M.A. Sparks, D. Chen, M. Herrera and T.M. Coffman

Duke University Medical Center, Durham, NC, USA

The renin-angiotensin system (RAS) is a key regulator of blood pressure (BP), with angiotensin II (ang II) acting as a major effector molecule via its receptors which are broadly expressed in a variety of tissues. Previous and ongoing work from our lab has demonstrated the significance of the type 1 angiotensin receptor in the kidney for BP homeostasis. We have taken the approach of gene-targeting in mice to study the role of the AT1A receptor in BP regulation and hypertension pathogenesis. Mice completely deficient in AT1A receptors had profound reductions (>20 mm Hg) in systolic blood pressure. Following this, we next used a kidney cross-transplantation approach to identify the kidney as a tissue with a distinct role in BP regulation by the RAS. Kidney AT1A KO mice had lower baseline BPs and were resistant to angiotensin II hypertension. Our more recent studies have investigated the function of the AT1A receptor in BP control in individual cell lineages in order to dissect the role of the RAS in specific regions of the kidney. To accomplish this, we utilized a *cre*-loxp approach for cell-specific gene targeting using a mouse line we generated with a conditional *Agtr1a* allele. We have systematically examined the role of the AT1A receptor in BP regulation in the renal proximal tubule, distal nephron and renal vasculature. Our studies have identified critical segments in the kidney for baseline blood pressure homeostasis, salt sensitivity, and regulation of hypertension. Together, our data suggest that type 1 angiotensin receptors in the kidney play a complex role in the integrated control of blood pressure.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Sympathetic vasomotor control by oxidative stress in renovascular hypertension

E.B. Oliveira Sales[1], R.R. Campos[1] and J.F. Paton[2]

[1]Physiology, Federal University of Sao Paulo, Sao Paulo, Brazil and [2]Physiology, University of Bristol, Bristol, UK

There is mounting evidence that increased oxidative stress and sympathetic nerve activity play important roles in renovascular hypertension. In the present study, we tested whether enhanced superoxide signaling in RVLM of 2 kidney-1 clip rats (2K-1C) contributes to the chronic hypertension via sympathetic activation in conscious rats. In our previous studies, we identified an increase in AT1 angiotensin II receptor expression and in oxidative markers within the RVLM of 2K1C rats. Furthermore, tempol or vitamin C acute administration into the RVLM or systemically reduced blood pressure and renal sympathetic activity in 2K-1C but not in control rats. Thus, in this study, we enhanced superoxide scavenging into the RVLM by overexpressing cytoplasmically targeted superoxide dismutase enzyme using an adenoviral vector (Ad-CMV-CuZn-SOD) in Wistar rats (male, 150 to 180 g) in which the left renal artery was occluded partially 3 weeks earlier. Hypertension was documented using 24 hour radio-telemetry recording of arterial pressure (AP) and heart rate (HR) in conscious freely-moving rats. Hey Presto software (Waki et al, 2006) was used to calculate indices of autonomic function from the AP and HR variability by spectral analysis. Renovascular hypertension elevated both serine phosphorylation of p47phox subunit of NADPH and superoxide levels within the RVLM. The elevated superoxide levels were normalized by expression of CuZnSOD in the RVLM. Moreover, the hypertension produced in the 2K-1C rats was reversed 1 week after viral-mediated expression of CuZnSOD. This antihypertensive effect was maintained and associated with a decrease in the low-frequency spectra of systolic blood pressure variability, suggesting reduced sympathetic vasomotor tone. The expression of CuZnSOD was localized in the RVLM neurons, of which some contained tyrosine hydroxylase (C1 neurons). None of the above variables changed in control rats receiving Ad-CMV-eGFP in the RVLM. In renovascular hypertension, superoxide signaling in the RVLM plays a major role in the generation of increased sympathetic vasomotor tone and the chronic sustained hypertension.

Mice with selective angiotensin type 1A receptor deletion from catecholaminergic neurons show altered angiotensin II-dependent hypertension

A.M. Allen[1], N. Jancovski[1], J.K. Bassi[1], A.A. Connelly[1], J. Brandi[1], E.A. Stevens[1] and G.A. Head[2]

[1]Physiology, University of Melbourne, Parkville, VIC, Australia and [2]Neuropharmacology, Baker IDI Research Institute, Melbourne, VIC, Australia

Background: Angiotensin II (AngII) acts via several tissues, including the brain to exert its well established roles in the regulation of blood pressure (BP) and fluid and electrolyte regulation. Manipulation of brain AngII can also induce metabolic changes including lean phenotype and increased metabolic rate possibly via modulation of the sympathetic nervous system. These actions are mediated via activation of the AngII type 1A receptor (AT1AR). In addition, chronic low dose infusion of Ang II induces hypertension via activation of the AT1AR. Whilst the involvement of AT1AR in specific cells of the kidney has been demonstrated in AngII-dependent hypertension it is not clear whether other tissues are involved. The present study aimed to investigate whether targeted deletion of AT1ARs from the catecholaminergic cells affects the baseline metabolic parameters and blood pressure (BP) and the response to sustained infusion of AngII. Methods: All experiments were approved by the University of Melbourne Animal Experimentation Ethics Committee in accordance with guidelines of the Australian National Health and Medical Research Council. Mice (C57Bl/6 background) with cell-selective deletion of the AT1AR from catecholaminergic cells were generated by crossing AT1AR floxed (AT1ARfl/fl) mice with mice expressing cre-recombinase (Cre) under the control of the tyrosine hydroxylase (TH) promoter. Two different genotypes AT1ARfl/fl;TH-Cre+/- (knockouts) and AT1ARfl/fl;TH-Cre-/- (controls) were used in this study. In vitro autoradiography was performed to confirm the loss of AT1R binding from catecholaminergic cells. All surgical procedures were performed under surgical anesthesia (loss of pedal withdrawal reflex) using either isoflurane delivered by a gas mask (~2% in oxygen) or ketamine/xylacine i.p. (75 mg/kg:10 mg/kg). All animals received a long-acting, non-steroidal anti-inflammatory agent at the start of the surgical procedure (caroprofen 5 mg/kg). Telemetry devices were used to record baseline BP and heart rate (HR). For the metabolic studies, mice were housed individually in metabolic cages with free access to food and water. After 1 day acclimatization 24 hour urine output and food and water intake were recorded. AngII-dependent hypertension was induced by subcutaneous implantation of mini-osmotic pumps designed to infuse Ang II (500 ng/kg/min) for 4 weeks. Results: AT1R binding was completely absent in the adrenal medulla and thoracic sympathetic ganglia of the AT1AR fl/fl;TH-Cre+/- mice. Basal systolic BP and HR were not different between the groups (mean±SEM; 109± 1mmHg vs. 108 ± 2 mmHg and 553± 10 bpm vs. 573 ± 10 bpm). Body weight, water intake, and 24 h urine volumes were also not different between groups. Infusion of Ang II in AT1ARfl/fl;TH-Cre-/- induced a gradual pressor response that was increased above baseline by day 5 of infusion. The maximal change in BP occurred at day 13. After day 17 BP gradually decreased toward baseline. The trajectory of BP increase was less in the AT1A fl/fl;TH Cre+/- mice throughout the infusion with a significant decrease in the maximal response at day 13 of infusion (150± 3 mmHg vs. 133 ± 2 mmHg; $P<0.05$). The reduced pressor response was associated with reduced fluid and electrolyte retention, reduced activation of the sympathetic nervous system and loss of superoxide formation in key brain cardiovascular nuclei. Conclusions: AT1AR knockout from catecholaminergic cells does not elicit changes in metabolic state, baseline systolic BP or HR but expression of the receptor by these cells is essential for the full development of AngII hypertension.

SA380

Contributions of vascular inflammation in the brainstem for neurogenic hypertension

H. Waki

Physiology, Wakayama Medical University School of Medicine, Wakayama, Japan

Essential hypertension is idiopathic; however, it is accepted as a complex polygenic trait with underlying genetic components that remain unknown. Our supposition is that the pathogenesis of primary hypertension involves the activation of the sympathetic nervous system. In this symposium, I will summarize our findings obtained from experimental animal models of hypertension and introduce new mechanisms of neurogenic hypertension.

One pivotal region controlling the arterial pressure set point is the nucleus tractus solitarii (NTS). Since bilateral microinjection of $CoCl_2$, a non-selective blocker of neurotransmission, into the NTS of an animal model of human hypertension (the spontaneously hypertensive rat: SHR) resulted in an attenuated pressor response compared to normotensive Wistar Kyoto (WKY) rats (H. Waki, unpublished data). We therefore propose that alterations in the electrical excitability state of neurons in the NTS could be involved, at least in part, in the mechanisms underlying neurogenic hypertension in the SHR.

By performing whole-genome expression profiling on NTS tissues, we found that pro-inflammatory molecules, such as junctional adhesion molecule A (JAM-A) and leukotriene B4 (LTB4), were over-expressed in the NTS in SHRs compared to WKY rats [1, 2]. We also observed the accumulation of endogenous leukocytes inside capillaries within the NTS of SHRs and JAM-A- and LTB4-over-expressing rats [1, 2]. We also confirmed functionally that high levels of JAM-A and LTB4 may, in part, contribute to the development of neurogenic hypertension, and are not secondary to hypertension [1, 2]. Importantly, recent findings further confirmed that JAM-A may be involved in the etiology of not only SHRs but also other animal models of hypertension [3] and essential hypertension in humans [4].

The next question we addressed was how these high levels of pro-inflammatory molecules in the NTS can cause neurogenic hypertension. Despite the specific inflammatory state in the NTS of SHRs, which may be genetically programmed, the transcripts of some inflammatory molecules, such as chemokine (C–C motif) ligand 5 (Ccl5) and its receptors, chemokine (C–C motif) receptor 1 and 3, were down-regulated in the NTS of SHRs compared to WKY rats [5]. This may be a compensatory mechanism to avoid further strong inflammatory activity. Supporting this hypothesis, we found that a high level of LTB4 in the NTS could reduce Ccl5 transcript levels [5]. More importantly, we found that down-regulation of Ccl5 in the NTS of SHRs may be pro-hypertensive, since microinjection of Ccl5

into the NTS of SHRs decreased arterial pressure, but was less effective in WKY rats [5]. Since Ccl5 receptors are involved in the modulation of glutamate transmission from glutamate nerve endings, we hypothesize that the down-regulation of Ccl5 in the NTS may directly affect NTS neurons and hence result in the development of neurogenic hypertension in the SHR.

In addition to the above theory for the etiology of hypertension, we hypothesized that localized hypoxia in the NTS may also have a role in neurogenic hypertension [6]. The accumulation of leukocytes in the NTS microvasculature may induce an increase in vascular resistance and hypoperfusion within the NTS; the latter may trigger focal hypoxia, which may affect central neural cardiovascular activity. Therefore, we explored whether increased vascular resistance, low blood perfusion, and low oxygen delivery localized to the NTS can increase arterial pressure. We measured cardiovascular parameters before and after specific branches of the superficial dorsal medullary veins were occluded; we assumed these were drainage vessels from the NTS and their occlusion would produce stagnant hypoxia [7]. Following vessel occlusion, blood flow in the dorsal surface of the medulla oblongata, including the NTS region, showed an ~60% decrease and was associated with hypoxia in neurons located predominantly in the caudal part of the NTS, as revealed by using Hypoxyprobe-1, which is a marker for cellular hypoxia [7]. Arterial pressure increased and this response was significantly pronounced in both magnitude and duration when baroreceptor reflex afferents were sectioned [7]. These results suggest that localized hypoxia in the NTS increases arterial pressure. We propose that this represents a protective mechanism whereby the elevated systemic pressure is a compensatory mechanism to enhance cerebral perfusion. We assumed that this physiological mechanism may also be involved in the pathogenesis of neurogenic hypertension [6, 7].

All told, we suggest that vascular inflammation within the brainstem leads to elevated sympathetic nerve activity by multiple pathways in neurogenic hypertension.

Advent of the coronary circulation: Comings and goings among most of the world's vertebrates

T. Farrell, G. Cox, N. Farrell and H. Jourdan

University of British Columbia, Vancouver, BC, Canada

The embryonic development of a coronary circulation in birds and mammals occurs in concert with myocardial compaction, likely in response to myocardial hypoxia and the work of a cardiac chamber. Whether similar driving forces featured prominently during the evolution of the coronary circulation among chordates remains a mystery, in part because the arrangements for supplying oxygen to fish hearts are far more diverse than a simple coronary supply to compact myocardium. Indeed, it may be that the majority of fish species do not have a coronary circulation! As evident from extant cyclostome fishes, the archetype chambered, myogenic heart probably had no coronary circulation; a spongy ventricular myocardium receives its oxygen supply from systemic venous blood. Instead, the coronary circulation likely made its first appearance with the appearance of a jaw and a vertebral column advent in the elasmobranch fishes. While all elasmobranchs have compact myocardium in variable amounts in their ventricle, all boney fishes (teleosts) do not have a coronary circulation, suggesting an evolutionary loss of this cardiac oxygen supply route, a feature that persists in extant amphibians. Molecular phylogenies have shown where losses have occurred. Thus, many fish do not need a coronary circulation, even if the heart's oxygen supply is precariously dependent on oxygen-depleted venous blood. Thus, beyond the highly developed coronary circulations of endothermic sharks, salmonids and tunas, cardiac evolution showed movement away from coronary dependence, beginning perhaps with the cyprinid lineage and persisting at least through to the amphibians. . The degree of ventricular compaction in boney fishes, in part, is tied to athleticism, as shown by salmon and tunas, suggesting a close tie between the degree of compaction and cardiac workload. Nevertheless, salmon can survival and swim after coronary artery ligation, which suggests only a facultative dependence under certain situations. In fishes, the fact remains that a coronary circulation is always associated with compact myocardium and this is true for cardiac muscle of the ventricle as well as the cardiac muscle of the outflow tract, the conus arteriosus. Where the greatest mystery lies is with the forerunners of the tetrapod lineage, the lungfishes and coelocanths, and with the extant species of basal teleosts, many of which breathe air as well as water. Often these fishes lack compact myocardium in their ventricle, but possess a coronary circulation, which raises the question of coronary vascularity in the spongy myocardium. While the evolution of air breathing in fishes certainly increased the security of the cardiac oxygen supply by bringing better-oxygenated blood to spongy myocardium, it clearly did not supplant the need for a coronary circulation. Curiously, the early evolution of cardiac compaction and a coronary circulation also introduced the possibility of coronary arteriosclerosis since it is very prevalent in migratory salmon.

Cardiovascular function in fish: consequences from life in a chronically heated environment

E. Sandblom[1], A. Ekström[1], T. Aho[3], F. Sundström[2] and F. Jutfelt[1]

[1]Dept of Biological and environmental sciences, University of Gothenburg, Gotheburg, Sweden, [2]Dept of Animal Ecology, Uppsala University, Uppsala, Sweden and [3]Institute of Coastal Research, Swedish University of Agricultural Sciences, Öregrund, Sweden

Global climate change is predicted to continue with increasing average temperatures and more frequent temperature extreme events. This will have a profound impact on ectothermic animals such as fish where the body temperature and metabolism is directly determined by the ambient temperature. Current prevailing hypotheses suggest that insufficient oxygen transport is a primary limitation for ectothermic animals at elevated temperature, but knowledge about the adjustments to the cardiorespiratory system in fish during long-term warming (i.e. via acclimation and genetic adaptation) is still limited. Results from a recently launched research project on cardiovascular and respiratory function in Eurasian perch (Perca fluviatilis) that live and reproduce in the chronically heated 'Biotest enclosure' in the Baltic Sea off the nuclear power plant in Forsmark in Sweden will be presented and discussed. Cooling water from the nearby nuclear reactors has been directed to the 90 hectare enclosure since 1980 keeping water temperatures 5-10°C above ambient for over 30 years, but at otherwise the same abiotic conditions as the surrounding archipelago. Thus, this experimental facility presents a unique opportunity to study the physiological responses to chronic warming in a wild fish population. Preliminary results reveal that fish from the Biotest enclosure have smaller hearts relative to their body mass, and they are considerably more tolerant to acute temperature increase and better able to maintain cardiac function during acute thermal challenges. In addition, they have a depressed metabolic rate and a lower resting heart rate due to a higher cholinergic tone and a reduced intrinsic cardiac pacemaker rate relative to fish from outside the enclosure when compared at the same temperature.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA384

Control of pacemaker HCN channel function by cAMP and voltage

E. Accili

University of British Columbia, Vancouver, BC, Canada

Pacemaker HCN channels contribute to pacing in the mammalian sinoatrial node (SAN) (1), a region of the heart that determines natural beating rate, as well as in other species such as frog (2) and even the most basal chordates (3,4). Pacemaker channels are unusual in that they are opened by hyperpolarization and bind cAMP, which facilitates opening. Here, I discuss recent findings on how this channel is unusually modified by cyclic nucleotides and voltage.

Take a deep breath: cellular adaptations for life without oxygen

G.L. Galli

Faculty of Life Sciences, The University of Manchester, Manchester, England, UK

For most animals, oxygen is essential for the continual function of cellular processes. The absence of oxygen, termed anoxia, is associated with a number of pathological states such as ischemia, stroke, angina and cancer. Remarkably, certain vertebrates have evolved to live without oxygen for days, weeks and even months. Anoxia tolerance in these animals is derived from a wide array of physiological adaptations. As the study of ectothermic physiology advances, the cellular mechanisms underlying these adaptations are becoming resolved. Mitochondrial function is of particular interest, as it is the final arbitrator of life and death during oxidative stress. In particular, regulation of the F1F0 ATPase (Complex V of the electron transport chain) is emerging as a fundamental component of mitochondrial and cellular anoxia survival across vertebrates. A reduction in Complex V activity serves to preserve precious ATP supplies during acute anoxia and may protect against reactive oxygen species generation. Recent data suggests a down-regulation of Complex V is also characteristic of long term anoxic survival. Importantly, this anoxic survival strategy has been identified in all classes of vertebrates, which suggests fundamental mechanisms have been conserved throughout the animal kingdom to endure periods without oxygen.

SA386

Gaining control, the role of the contractile element in the evolution of muscle function

T. Gillis

University of Guelph, Guelph, ON, Canada

Evolutionary processes have increased the complexity and functional capability of the vertebrate heart. This includes the transformation of the single chambered found in tunicates heart to the teleost heart with one ventricle and one atrium to the four-chambered organ found in mammals and birds. Associated with these anatomical changes was a parallel increase in heart rate that enabled increased cardiac output. What is the same, however, in all myocardium is that contraction is generated using a similar collection of component proteins. Muscle contracts when intracellular Ca increases and binds to the contractile element via cardiac troponin C (cTnC). The activation of cTnC triggers a series of conformational changes through the components of the thin filament that results in the generation of force by the myocyte. While all muscle contraction is powered by this mechanism, comparison of contractile function between vertebrate species reveals significant variation. This includes differences in the rate of myocyte contraction and relaxation, in the strength of contraction as well as in functional response following the activation of protein kinases with β-adrenergic stimulation. This seminar will examine the functional basis for these differences and how these have evolved within the vertebrate heart. Specific focus will be placed on cardiac troponin I (cTnI) and cardiac myosin binding protein C (cMyBP-C) and how these proteins have evolved to regulate contractile function in the vertebrate heart. Both cTnI and cMyBP-C are targets for phosphorylation following β-adrenergic stimulation in the mammalian heart. The influence of the evolution of endothermy on the function of the contractile element is also considered, as is the ability of hearts from specific species to function over a variety of physiological conditions. This analysis is completed through the integration of functional studies that have examined the role of specific proteins in regulating cardiac function with studies that have utilized phylogenetic approaches to examine the evolution of specific proteins and how this relates to key functional traits. It is generally found that as the heart became more complex in both anatomy and functional capacity, changes in protein sequence enabled improved control of the contractile reaction. In addition, the evolution of endothermy appears to have driven changes in the function of specific proteins including cTnC, cTnI and cMyBP-C. It is hoped that this integration of functional and phylogenetic studies will provide new insight into the role that the contractile element plays in regulating cardiac function and how this has evolved in vertebrates.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA387

Plasma membrane estrogen receptors and the biology of estrogen action

E.R. Levin

University of California, Irvine and the Long Beach VA, Irvine, CA, USA

Estrogen receptors exist in many cellular pools throughout most organs. This is true for the alpha and beta isoforms that are responsible for the actions of the sex steroid on normal organ development and function, and both opposing and promoting organ pathophysiology. Although many additional proteins have been speculated to act as estrogen receptors, scant evidence supports this role. In contrast, classical ERα and ERβ are found in multiple cellular pools, and only the complete knockout of these receptors produces a profound series of phenotypes that define the important functions of these sex steroid receptors. However, total deletion of the classical receptors does not inform us of the contributions of each cellular pool. We therefore have made transgenic mice, representing the selective loss of the nuclear receptor pool (membrane-only ERalpha (MOER) mice) or loss of the membrane pool (nuclear-only,NOER) mice. Using these mice, we have defined unique phenotypes, novel gene regulatory mechanisms, and metabolic signatures. For most complex organ development and biological functions, both membrane and nuclear ERα are generally required but in specific ways.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Membrane initiated estrogen actions on the cytoskeleton

M. Kampa, V. Pelekanou, G. Notas and E. Castanas

Laboratory of Exp.Endocrinology, School of Medicine, Univesity of Crete, Heraklion, Crete, Greece

During the last decade our knowledge on estrogen action has been highly enriched by new data on their ability to exert rapid effects that are initiated at the membrane and activate a number of membrane related kinases and subsequently modify intracellular signaling cascades. One of the major targets of membrane initiated action of estradiol in a variety of cell types is actin cytoskeleton. Cytoskeletal modifications are of great importance since they can lead to changes in a wide range of cellular functions. More specifically estradiol has been shown to induce endothelial remodeling (Simoncini et al, 2006), axonal growth (Sanchez et al, 2009) and modulate cell migration of both normal (e.g. endometrial stromal cells) (Flamini et al, 2011) and cancerous (e.g. breast cancer cells) (Kampa et al, 2008, Sanchez et al, 2010) cells. Indeed in breast cancer, estrogens have been reported to induce actin cytoskeleton redistribution that favors cell migration which is required for cancer cell invasion and metastasis. Their action occurs through membrane estrogen receptors that trigger specific signaling events, involving G proteins, small GTPases, src, FAK, cdc42 and N-WASP. Even though the nature of membrane estrogen receptor has not been fully elucidated, it has been shown both biochemically (Sanchez et al, 2010) and verified by our group by a transcriptome analysis that the membrane receptor involved in this cytoskeletal action is ERα (Kampa et al, 2012).

Interestingly, this is not the only role for ERα, which has in its sequence an interesting motif (P295-T311) that is located between the D- (hinge) and E- (Ligand Binding Domain) regions, in the autonomous activation function AF-2a, and is considered as an important platform for various post-translational modifications and calmodulin binding. In fact a peptide corresponding to this motif (ERα17p) that could be liberated after the proteosomal degradation of ERα, we have equally found to induce rapid actin cytoskeleton re-arrangements and affect cell migration independently of the presence of ERα (Kampa et al, 2011) . This finding is very interesting since ERα bearing cells can affect the migration of ER negative cells and modulate one of the major problems of breast cancer, metastasis.

The G-protein-coupled estrogen receptor GPER in health and disease

M. Barton

Molecular Internal Medicine, University of Zurich, Zurich, Switzerland

Estrogens importantly contribute to physiological homeostasis and exert their effects through genomic and non-genomic ("rapid") actions [1, 2]. Rapid signaling of estrogen, which has been first reported in the 1960s [3-5] involves membrane estrogen receptors (ERs), including membrane subpopulations of ERalpha and ERbeta. In the early 1990s, rapid increases in cyclic AMP in response to estrogen were reported in human coronary arteries as well as in mammary and uterine cells [6, 7]. Shortly thereafter, several laboratories independently reported the cloning of an orphan G protein-coupled receptor from vascular and cancer cells that was named GPR30 [8-11]. Research published between 2000 and 2005 provided evidence that GPR30 binds and signals via estrogen indicating that this intracellular receptor is involved in rapid, non-genomic estrogen signaling [12-14]. The receptor has since been designated as the G protein-coupled estrogen receptor (GPER) by the International Union of Pharmacology [15]. The availability of genetic tools such as different lines of GPER knock-out mice, as well as GPER-selective agonists and antagonists has advanced our understanding, but also added some confusion about the new functions of this receptor (reviewed in [16]). Research of the past decade has provided evidence that GPER is critically involved in the regulation of vascular tone and blood pressure, metablic control [17], inflammation, and reproductive biology, among others. It is important to note that GPER not only binds estrogens but also other substances, including SERMs, SERDs, and environmental ER activators (endocrine disruptors; xenoestrogens) and also interacts with other proteins [18]. The current knowledge and unresolved questions about GPER-dependent signaling and function in health an disease will be discussed, as well as controversies that have complicated our understanding of GPER function, including interactions with human ERa-36 and aldosterone as a potential ligand [18].

Estrogen regulation of KCNQ1:KCNE3 channels in intestinal secretion

R. Rapetti-Mauss, V. Urbach and B.J. Harvey

Department of Molecular Medicine, Royal College of Surgeons in Ireland, Dublin, Ireland

Estrogen, 17-βestradiol (E2), rapidly reduces cAMP-dependent intestinal Cl^- secretion by inhibiting K^+ recycling (1). KCNQ1:KCNE3 is the rate-limiting K^+ channel involved in Cl^- secretion in the colon (2) and E2 rapidly inhibits KCNQ1 current in the female rat distal colon by a gender-specific mechanism (3). Regulation of KCNQ1 surface density has been shown to play a role in the control of KCNQ1 activity. Recently we demonstrated that estrogen rapidly uncouples KCNQ1 from its regulatory beta subunit KCNE3 causing a decrease in channel conductance (4). The aim of this study was to determine if membrane trafficking plays a role in the E2 inhibition of KCNQ1 function in the human colonic cell line, HT29cl19A. Ussing chamber ion transport measurements, biotinylation assays and immuno-staining have been used to study the effect of 10nM E2 treatment on KCNQ1 current and protein cellular localization. Protein expression was determined by Western blotting assay. All results are given as the mean ± S.E.M. Statistical significance was established using one-way ANOVA followed by a Tukey's post hoc test or a Student t test where relevant.

E2 (10 nM) reduced both forskolin-induced Cl^- secretion (30 ± 6 % n=6 $p<0.05$) and KCNQ1 activity (45 ± 8 % n=4 $p<0.05$) in HT29 cells monolayer. KCNQ1 was removed from the plasma membrane and internalized in cytosolic pools after 15 min E2 treatment (n=5). A biotin internalization assay confirmed this observation (internalized KCNQ1 after E2 treatment = 200 ± 9.9 % of control, n=5, $p<0.001$). Our results suggested that KCNQ1 internalization is clathrin and dynamin dependent since chlorpromazine and dynasore reversed E2 mediated KCNQ1 internalization as shown by immunofluorescence (n=4). Fluorescence co-localization studies indicated that KCNQ1 rapidly co-localized with the clathrin adaptor AP2 μ2 (Adaptor Protein 2 sub-unit μ2) 10 min after E2 treatment (overlap coefficient (O.C.) = 0.28 ± 0.04, control – 0.77 ± 0.01 E2, n=4). Following internalization, a subset of KCNQ1 appeared to accumulate in early endosomes (EE), (EE marker, EEA-1; O.C. with KCNQ1 = 0.30 ± 0.07% control, 0.60 ± 0.04 E2, n=4, $p< 0.05$). Further experiments revealed that KCNQ1 is recycled to the membrane rather than degraded. Following E2 exposure KCNQ1 rapidly co-localized with Rab4 (O.C. = 0.31 ± 0.02, control, 0.64 ± 0.02 E2 15 min), but Rab11 co-localization was only observable after 120 min (O.C. = 0.3 ± 0.03 control, 0.67 ± 0.01, E2) suggesting that KCNQ1 is sorted from the EE to the recycling endosomes. After 240 min exposure to E2, 70 ± 5 % (n=6, $p<0.001$) of internalized KCNQ1 was recycled back to the membrane as shown by the biotin recycling assay. Following E2 treatment, PKCδ (287 ± 51 % n=4, $p<0.05$) and AMPK (232 ± 24%, n=5, $p<0.05$) phosphorylation were increased within 2 min exposure to E2. Immuno-staining and biotinylation experiments revealed that E2 failed to induced KCNQ1 endocytosis in HT29cl19A cells when pre-treated with BIS1 a general PKC inhibitor, rottlerin a potent PKCδ inhibitor or Compound-C a AMPK inhibitor (n=4). Interestingly, we also demonstrated that KCNQ1 rapidly associates with Nedd4.2, an ubiquitin ligase, in response to estrogen treatment (346 ± 56% n=3, $p<0.001$). The last results suggest that E2 induces KCNQ1 ubiquitination to stimulate channel internalization.

This study establishes a role for E2 in the regulation of KCNQ1 cell surface abundance. In conclusion, we propose that the internalisation of KCNQ1 is a rapid estrogen response in modulating intestinal secretion.

Oestrogen receptor beta: a new target for type 2 diabetes treatment

P. Alonso-Magdalena[1], A.B. Ropero[1], M. García-Arévalo[1], S. Soriano[1], I. Quesada[1], S.J. Muhammed[3], A. Salehi[3], J. Gustafsson[2] and A. Nadal[1]

[1]Universidad Miguel Hernandez de Elche, Elche (Alicante), Spain, [2]University of Houston, Houston, TX, USA and [3]University of Lund, Malmö, Sweden

The estrogen receptor beta (ERbeta) is emerging as an important regulator of pancreatic beta cell function (Soriano et al, 2009). Here we have evaluated the role of the ERbeta selective agonist, WAY200070, as an insulinotropic molecule and its antidiabetic actions in CB57 mice. We have demonstrated that it enhances glucose-stimulated insulin secretion (GSIS) both in mouse and human islets of Langerhans. In vivo experiments showed that a single-administration of WAY 200070 leads to an increase in plasma insulin levels with a concomitant improved response to a glucose load. Two-week treatment increased GSIS, pancreatic beta-cell mass and improved glucose and insulin sensitivity. In addition, streptozotocin-nicotinamide-induced diabetic mice treated with WAY200070 exhibited a significant improvement in plasma insulin levels and glucose tolerance as well as a regeneration of pancreatic beta-cell mass. Studies performed in db/db mice demonstrated that this compound restored first-phase insulin secretion, enhanced pancreatic beta-cell mass and favored the control of body weight. We conclude that ERbeta agonists should be considered as new targets for the treatment of diabetes (Alonso-Magdalena et al, 2013).

Long non-coding RNA & cancer

S. Diederichs

German Cancer Research Center, Heidelberg, Germany and Dept. of Pathology, University of Heidelberg, Heidelberg, Germany

The last decade introduced a paradigm shift in molecular biology towards the recognition of non-protein-encoding RNA molecules as functionally important players in physiological and pathological processes. These transcripts are frequently deregulated in tumors and may also exert tumor suppressive or oncogenic functions. Our research aims at elucidating the expression, regulation and function of long non-coding RNAs in lung, liver and breast cancer.
In detail, I will present our discovery of the lncRNA MALAT1 as a biomarker for lung cancer metastasis and the generation of a novel loss-of-function model in human cells unraveling the active function of MALAT1 as a regulator of gene expression governing lung cancer metastasis.
We also provide the first global comprehensive map of long ncRNA expression in a broad range of human tumor and normal tissue samples and discovered many new lncRNAs associated with cancer as well as tissue-, histology- and prognosis-specific ncRNA signatures. First data shed light onto the important functions of these newly discovered lncRNAs at the cellular and molecular level.

Human nuclear dicer restricts accumulation of endogenous double strand RNA

M. Gullerova

University of Oxford, Oxford, UK

Dicer is a central enzymatic player in RNA interference (RNAi) pathways that acts to regulate gene expression in nearly all eukaryotic cells. In mammals, the well documented cytoplasmic role of Dicer in generating small interfering (si) and micro (mi)RNA, is known to lead to the selective degradation and translational repression of messenger (m)RNA. The view persists that mammalian Dicer has no direct nuclear function, even though in other eukaryotes such as plants, drosophila, C. elegans5 and some yeast the nuclear role of Dicer in transcriptional gene silencing (TGS) through siRNA formation is well established. More recent analysis of potential mammalian nuclear RNAi has revealed that it is possible to induce TGS by nuclear RNAi pathways and also that loss of Dicer can directly impact on genic and intergenic transcriptional activity. Here we show unequivocally that Dicer is present in both the nucleus and cytoplasm, but that its nuclear levels are tightly regulated. In its nuclear manifestation Dicer interacts with RNA polymerase II (Pol II) at actively transcribed gene loci. Loss of Dicer causes the immediate appearance of endogenous dsRNA leading to induction of the interferon response pathway and consequent cell death. Our results suggest that Pol II associated Dicer restricts endogenous dsRNA formation, presumably from overlapping non-coding RNA transcription units (natural antisense RNA). Failure to do so has catastrophic effects on cell function. Taken together, we present here a miRNA independent role for human nuclear Dicer.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA394

RNA regulation in male germline

N. Kotaja

Department of Physiology, Institute of Biomedicine, University of Turku, Turku, Finland

Germ cells are unique in their capability to give rise to a new organism. In addition to genetic information, the epigenetic status of cells is inherited, which emphasizes the importance of securing both genetic integrity and correct epigenetic marks in the germline. The alarming decline in the semen quality and reproductive health in Western countries has unveiled the necessity of understanding the genetic, epigenetic and environmental factors governing male reproductive functions. Male germ cell differentiation is orchestrated by accurate, spatially and temporally controlled gene expression patterns. Male germ cells express outstanding amount of different non-coding RNAs, including both small RNAs and yet poorly characterized long non-coding RNAs. Small non-coding RNAs are important regulators of gene expression that mainly function at the post-transcriptional level. Small RNAs produced by the male germline include Dicer-dependent microRNAs (miRNAs) and endogenous small interfering RNAs (endo-siRNAs), and Dicer-independent piwi-interacting RNAs (piRNAs).
The goal of our research is to clarify the roles of non-coding RNAs and the mechanisms of post-transcriptional gene control during male germ cell differentiation. We have shown that Dicer-dependent pathways are required for normal spermatogenesis and male fertility by analyzing a knockout mouse model to delete Dicer1 gene specifically in early postnatal male germ cells. Our results demonstrate that Dicer is crucial for the correct nuclear polarization and chromatin condensation of developing spermatids. piRNAs that are expressed predominantly in the germline form a big, complex and functionally diverse group of small RNAs. piRNA expression is known to be greatly induced in late meiotic cells and round spermatids, and interestingly, we have shown that in these cells, piRNAs accumulate in an intriguing male germ cell -specific cytoplasmic ribonucleoprotein granule, a chromatoid body (CB). We have isolated CBs from mouse testis and identified its molecular composition by mass spectrometric analysis and RNA sequencing to better understand its functions in haploid cells. The CB appears to act as a central RNA regulation platform as it accumulates a multitude of different RNA-binding

and RNA-processing proteins as well as several RNA species including piRNAs, mRNAs and long non-coding RNAs. All the results indicate that the CB has an important role in the regulation of meiotic and post-meiotic processes. Many of the CB components are essential for normal spermatogenesis in mouse, which highlights the significance of this structure in maintaining male fertility.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA395

Spontaneous activity patterns in the developing mouse visual cortex

C. Lohmann

Synapse and Network Development, Netherlands Institute for Neuroscience, Amsterdam, Netherlands

The developing brain generates spontaneous activity even before our senses are activated. This spontaneous activity is transmitted along neuronal pathways and is required for setting up precise connections between nerve cells. How specific activity patterns are translated into precise patterns of connectivity is currently unknown. To start addressing this question, we are investigating the patterns of spontaneous activity in the developing visual cortex using in vivo calcium imaging and electrophysiology. We discovered two types of spontaneous activity that are characterized by low and high levels of synchronization between neurons: L- and H-events, respectively. Manipulating peripheral spontaneous activity, i.e. retinal waves shows that L-events are largely driven by retinal inputs. In contrast, H-events are centrally generated. Here, I will discuss the characteristics of these activity patterns from the synaptic to the network level and propose ideas about how these activity patterns may guide the development of specific connections in the developing visual system.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA396

Structural correlates of visual cortex plasticity

T. Keck

MRC Centre for Developmental Neurobiology, King's College London, London, UK

Sensory experience is widely thought to drive activity levels in the cortex. In adult animals, chronic modifications of sensory activity, such as visual deprivation, lead to compensatory changes in synaptic strength. The postsynaptic mechanisms that underpin modifications of synaptic strength have been studied in great detail. In contrast, the presynaptic mechanisms that are altered following a change in cortical activity are less well understood. Here we study presynaptic axonal boutons of excitatory axons in superficial layers of the adult mouse primary visual cortex following enucleation. We found greater bouton turnover at excitatory axons in the cortex of mice with reduced visually driven activity (deprived). Persistent boutons fluctuated in a size dependent manner; so that large boutons became smaller whilst smaller boutons became bigger. This shift in the synaptic 'weighting' of individual boutons was balanced so that the population average remained constant. Functional analysis of the paired pulse ratio was consistent with a remapping of synaptic weights so that synaptic dynamics shifted from largely depression to a combination of weak depression and facilitation. One mechanism that might account for regulation of this process is the sharing of a finite pool of local presynaptic machinery. We propose that this is a form of presynaptic homeostasis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

***In vivo* imaging of coordinated excitatory and inhibitory synaptic dynamics on pyramidal cell dendrites**

K.L. Villa[1,2], K.P. Berry[1,2], J.L. Chen[1,2], J. Cha[3], P.C. So[3,4] and E. Nedivi[1,5]

[1]Picower Institute for Learning and Memory, Massachusetts Institute of Technology, Massachusetts, MA, USA, [2]Department of Biology, Massachusetts Institute of Technology, Massachusetts, MA, USA, [3]Department of Mechanical Engineering, Massachusetts Institute of Technology, Massachusetts, MA, USA, [4]Department of Biological Engineering, Massachusetts Institute of Technology, Massachusetts, MA, USA and [5]Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Massachusetts, MA, USA

A critical feature of brain plasticity is the capacity to dynamically adapt in response to the environment by remodeling connections between neurons. Inhibitory neurons are known to play a vital role in defining the window for critical period plasticity during development, and it is increasingly apparent that they continue to exert powerful control over experience-dependent cortical plasticity in adulthood. Recent *in vivo* imaging studies demonstrate that long-term plasticity of inhibitory circuits is manifested through structural rearrangements. Changes in sensory experience drive this structural remodeling of inhibitory interneurons in a cell type and circuit specific manner. We recently found that inhibitory synapse formation and elimination occurs with a great deal of spatial and temporal precision, and is often locally coordinated with excitatory synaptic changes on the same dendrite, largely clustered within a 10 um distance. Yet, the nature of the clustered inhibitory and excitatory synaptic dynamics remains temporally unresolved in terms of whether the two events occur simultaneously or if one of the two events drives the change, while the other adjusts to it. Does the presence of a dynamic inhibitory synapse destabilize neighboring spines, or do excitatory synaptic changes drive inhibitory synapse dynamics? Are the valence changes of coordinated events weighed in the same direction, or are they compensatory? I.e. does excitatory synapse loss drive formation or loss of an inhibitory synapse? To further probe the nature of 'coordination' between inhibitory and excitatory synaptic dynamics we triple-labeled L2/3 pyramidal neurons in the mouse visual cortex via *in utero* electroporation using YFP as a cell fill, PSD95-mcherry to label excitatory synapses, and Teal-Gephyrin to label inhibitory synapses. Upon reaching adulthood, these mice were implanted with cranial windows and labeled cells in binocular visual cortex were imaged *in vivo* at short intervals using spectrally resolved two-photon microscopy.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA398

The emergence of functional microcircuits in visual cortex

S. Hofer

University College London, London, UK and Biozentrum, University Basel, Basel, Switzerland

The ability of the brain to extract meaning from sensory stimuli depends on the computational capabilities of precisely connected neuronal networks in the cerebral cortex. Despite variations between cortical areas and species, neurons receiving similar inputs or sharing similar response properties often aggregate into fine-scale functional networks. In the mature visual cortex (V1), for example, neurons are not randomly connected, but form specific local and long-range circuits, which may influence the neuronal selectivity for different features of visual scenes, such as their orientation, direction and position. How such fine-scale functional circuits emerge during postnatal development from an immature neuronal network remains a fundamental question in neuroscience.
We are addressing this question in mouse V1 by directly relating patterns of excitatory synaptic connectivity to visual response properties of neighbouring layer 2/3 pyramidal neurons at different postnatal ages, using two-photon calcium imaging in vivo in anaesthetized mice and multiple whole-cell recordings in vitro. Our previous work revealed that pyramidal neurons connect preferentially if they respond similarly to visual stimuli. At eye-opening, although neural responses were already highly selective for visual stimuli, neurons responding to similar visual features were not yet preferentially connected, indicating that the emergence of feature selectivity does not depend on the precise arrangement of local synaptic connections. After eye opening, local connectivity reorganised extensively, as more connections formed selectively between neurons with similar visual responses, and connections were eliminated between visually unresponsive neurons, while the overall connectivity rate did not change. We propose a unified model of cortical microcircuit development based on activity-dependent mechanisms of plasticity: neurons first acquire feature preference by selecting feedforward inputs before the onset of sensory experience, after which patterned input drives the formation of functional subnetworks through a redistribution of recurrent synaptic connections.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA399

How sensory deprivation and learning change neuronal responses in mouse visual cortex

M. Hübener

Max Planck Institute of Neurobiology, Martinsried, Germany

Neuronal response properties in the brain are not static over time. They can change during development, after deprivation, and following learning. We study such functional plasticity with two-photon calcium imaging, using orientation selectivity in the mouse visual cortex as a model.

One way to alter orientation tuning in the visual cortex is stripe rearing, where animals are exposed to contours of only one orientation for a certain period. Earlier studies have shown that stripe rearing causes a relative overrepresentation of neurons in visual cortex tuned to the experienced orientation. It is not clear, however, whether these changes are merely due to a permissive effect, causing cells tuned to the non-experienced orientations to lose responsiveness, or whether the experienced orientation acts in an instructive fashion, such that some cells actively change their tuning. The main reason for this uncertainty is that with conventional methods it is difficult to assess the proportion of unresponsive cells. This problem can be overcome by two-photon calcium imaging, where all neurons are labeled, thereby allowing for an unbiased determination of the fraction of unresponsive cells.
We have raised juvenile mice for three weeks with cylinder lens goggles limiting visual experience to only one orientation. Following this period, orientation preference in the visual cortex was determined with two-photon calcium imaging. Stripe rearing changed the distribution of preferred orientations such that more cells responded to the experienced orientation than to the orthogonal orientation. The fraction of responsive neurons was lowered, but this effect could not fully account for the changes observed in the distribution of preferred orientations.
The magnitude of the stripe rearing effect increased with cortical depth: the distributions of preferred orientations changed only modestly in upper layer 2/3, but we noted a pronounced drop in the fraction of responsive cells. In contrast, neurons deeper in layer 2/3 did not change their overall responsiveness, but we found a clear shift towards the experienced orientation. Thus, diverse mechanisms contribute to the changes in preferred orientation following stripe rearing, but the effect is at least partially mediated by an instructive process, by which individual neurons change their orientation preference.
We next asked the question whether orientation tuning in the visual cortex also shows plasticity under behaviorally relevant conditions. During active vision, the visual cortex is subject to extensive feedback signaling and top-down modulations. However, in which way and to what extent the visual cortex is involved in visual perceptual learning remains highly controversial. We used repeated two-photon calcium imaging in anaesthetized mice over twelve days with the genetically encoded calcium indicator GCaMP3. Applying this technique, we quantified changes in orientation tuning in individual neurons in the visual cortex before, during and after orientation discrimination learning. While overall orientation preference was not affected, tuning width and response amplitude changed during learning in neurons with specific differential preferred orientations (with regard to the rewarded orientation). Strikingly, these changes were correlated with task performance. Moreover, we found a pronounced gain in the number of orientation-selective neurons in mice that performed well in the orientation discrimination task. These neurons were mostly tuned to the rewarded or the orthogonal orientation, pointing to an enhanced neuronal responsiveness to these orientations. These data support, in line with previously proposed theories, a reweighting of visual information during visual perceptual learning.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA400

Calcium dynamics in nano-junctions between the sarcoplasmic reticulum (SR), plasma-membrane and other organelles in vascular smooth muscle

C. van Breemen[1], N. Fameli[1], M. Esfandiarei[1] and A. Evans[2]

[1]Department of Anesthesiology, Pharmacology & Therapeutics, University of British Columbia, Vancouver, BC, Canada and [2]Centre for Integrative Physiology, University of Edinburgh, Edinburgh, UK

Physiological selection between different modes of cell function is based on the segregation of Ca^{2+} transients in different locations of the cytoplasm. Evidence in the literature suggests that in smooth muscle such segregation is effected by a large variety of specialized SR-organelle nano-junctions, each controlling the [Ca^{2+}] in a nano-space near Ca^{2+} sensitive enzymes, channels, pumps and exchangers (Pan-Junctional SR). If different parts of the Pan-Junctional SR generate different localized [Ca^{2+}], then it is likely that the SR itself is compartmentalized. However, it has been shown that the SR luminal Ca^{2+} concentration can be independently regulated via PM-SR junctions and that there is structural continuity throughout the SR and nuclear envelope. The answer to this paradox could be resolved by assuming that the SR lumen is irregular, has spatially separated clusters of sarco/endoplasmic reticulum Ca^{2+} ATPases (SERCA), inositol 1,4,5-trisphosphate receptors (IP_3R) and ryanodine receptors (RyR) and exhibits areas of restricted diffusion. Therefore, the nanospaces bordering both surfaces of the SR are critical in defining the specificity of the Ca^{2+} signals. In this presentation, we propose that the typical make-up of the Pan-junctional SR determines the smooth muscle type and pose the question of how to formulate a quantitatively testable hypothesis describing Ca^{2+} transport mechanism in junctions between the membranes of the SR and other organelles, including the plasma-membrane (PM).
All vascular smooth muscles respond to physiological stimulation with Ca^{2+} oscillations, but three different types of Ca^{2+} oscillations have been reported for various blood vessels:
1. Waves of Ca^{2+} induced Ca^{2+} release (CICR) involving IP_3R initiated by elevation of IP_3.
2. Waves of CICR involving RyR, initiated by nicotinic acid adenine dinucleotide phosphate (NAADP)-mediated lysosomal Ca^{2+} release.
3. Non wave-like Ca^{2+} oscillations paced by periodic SR Ca^{2+} release.
Since Ca^{2+} release channels exhibit Ca^{2+} sensitivity on both their cytoplasmic and luminal terminals, fluctuations in regional luminal Ca^{2+} can also function as pacemakers to determine the frequency of SR Ca^{2+} release waves and that of non-wave-like Ca^{2+} oscillations.
How do we test these provocative hypotheses?
At present, specific hypotheses borne out of experimental observations often yield only cartoon models and can hardly be verified by conventional experimental methods. We argue that realistic quantitative modeling of the stochastic processes characterizing ion transport in the junctions is a necessary tool on the one hand for testing of such hypothesis and on the other to generate further testable predictions on SR junction mechanisms.
We briefly overview a quantitative modeling approach that integrates the available experimental evidence into a realistic reproduction of two specific vascular smooth muscle SR junctions: (1) the PM-SR junction, which appears to be at the base of CICR wave phenomena originating from IP_3R Ca^{2+} release from the SR upon adrenergic stimulation; (2) the lysosome-SR junction, in which NAADP-mediated Ca^{2+} release from two pore segment channels type 2 (TPC2) seems to originate Ca^{2+} bursts, which cause cell-wide CICR at RyR.
Finally, we address the general question of how this approach could further our understanding of the coordinated regulation of such diverse processes as vaso-motor tone, metabolism and nuclear transcription.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

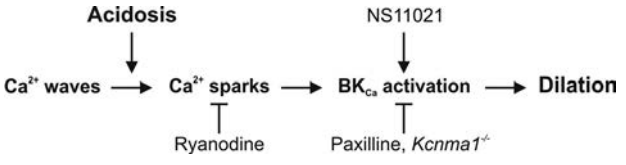
Acidosis dilates brain parenchymal arterioles by reshaping spontaneous calcium signals to activate BK_{Ca} channels

F. Dabertrand[1], M.T. Nelson[1,2] and J.E. Brayden[1]

[1]Pharmacology, University of Vermont - College of Medicine, Burlington, VT, USA and [2]Institute of Cardiovascular Sciences, Manchester, UK

Acidosis is a powerful vasodilator signal in the brain circulation. However, the mechanisms by which this response occurs are not well understood, particularly in the cerebral microcirculation. Ryanodine receptors (RyRs) are Ca^{2+} permeable channels in the sarcoplasmic reticulum. They dilate cerebral (pial) arteries by activation of large-conductance, calcium-sensitive potassium (BK_{Ca}) channels by local Ca^{2+} signals (Ca^{2+} sparks). This mechanism is clearly demonstrated by the non-additive constrictions induced by RyR or BK_{Ca} channel blockers in pressurized pial arteries. Nevertheless, these blockers have little effect on the diameter of pressurized parenchymal arterioles (PAs) from the brain, even though functional BK_{Ca} channels and RyRs are present. To determine the mechanism by which acidosis dilates brain PAs and to elucidate the roles of RyRs and BK_{Ca} channels in this response, internal diameter and vascular smooth muscle cell Ca^{2+} signals were measured in isolated pressurized murine PAs, using imaging techniques. At physiological pH (7.4) vascular smooth muscle cells exhibited largely Ca^{2+} waves but not Ca^{2+} sparks. Reducing external pH from 7.4 to 7.0 in both normocapnic and hypercapnic conditions decreased Ca^{2+} wave activity, and dramatically increased Ca^{2+} spark activity. Acidic pH caused a dilation of PAs which was inhibited by about 60% in a non-additive manner by BK_{Ca} channel blocker (1 μM paxilline) or RyR blocker (ryanodine 10 μM). Similarly, dilator responses to acidosis were reduced by nearly 60% in arterioles from BK_{Ca} channel knockout mice. Dilations induced by acidic pH were unaltered by inhibitors of K_{ATP} channels (1 μM glibenclamide) or nitric oxide synthase (100 μM L-NAME). These results support the novel concept that acidification, by converting Ca^{2+} waves to sparks, leads to the activation of BK_{Ca} channels to induce dilation of cerebral PAs.



Proposed mechanism for ryanodine receptors (RyRs)- and calcium-sensitive potassium (BK_{Ca})-dependent, acidosis-induced dilation of brain parenchymal arterioles. By decreasing the open probability of RyRs in vascular smooth muscle cells, protons reshape intracellular Ca^{2+} signaling from waves to sparks which activate BK_{Ca} channels and then cause dilation.

From contraction to gene expression: function-specific calcium signals are delivered by the strategic positioning of calcium pumps and release channels within membrane-membrane nanojunctions of the sarcoplasmic reticulum

A. Evans

Centre for Integrative Physiology, University of Edinburgh, Edinburgh, UK

Pulmonary arterial hypertension is driven by smooth muscle contraction and by the switch from a contractile to a migratory-proliferative smooth muscle phenotype(s), which requires changes in gene expression. These processes are selected, in part, by calcium signals, but how different calcium signals are generated to select each function is enigmatic.

We have previously shown that SERCA2b and RyR1 are preferentially targeted to the sarcoplasmic reticulum (SR) proximal to the plasma membrane (PM) in pulmonary arterial smooth muscle cells (PASMCs; Clark et al., 2010); i.e. to the superficial buffer barrier formed by PM-SR nanojunctions (van Breemen et al., 2013). Here they may support vasodilation in response to β-adrenoceptor activation. Induced increases in SERCA2b activity may thus remove calcium from the deeper cytoplasm to the superficial SR, from which calcium sparks may be released into the PM-SR junction via RyR1 to activate PM resident BKCa channels, driving hyperpolarisation (Boittin et al., 2003), removal of calcium from the cell by forward mode NCX activity and ultimately vasodilation (Boittin et al., 2003; Clark et al., 2010).

In marked contrast, SERCA2a is entirely restricted to the deep, perinuclear SR (Clark et al., 2010) and may function to recycle calcium into this sub-compartment in support of vasoconstriction (Dipp & Evans, 2001; Dipp et al., 2001; Kinnear et al., 2004; Clark et al., 2010). Importantly, differrent subtypes of RyR are also strategically positioned here. RyR3 is preferentially targeted to the perinuclear SR and associated lysosome-SR nanojunctions (Kinnear et al., 2004, Kinnear et al., 2008), while the distribution of RyR2 is more widespread and extends from this region to the wider cell (Kinnear et al., 2008; Clark et al., 2010). We therefore proposed that perinuclear clusters of RyR3 may act as an initiation site for propagating calcium waves and contraction (Dipp & Evans, 2001; Kinnear et al., 2008). Thereafter, by calcium-induced calcium release, RyR2 may carry propagating calcium waves away from perinuclear clusters of RyR3 and across the myofilaments to enhance myocyte contraction (Kinnear et al., 2008; Clark et al., 2010).

We have now identified a third subtype of SERCA pump in PASMCs, namely SERCA1, which together with RyR1 preferentially lines the nucleoplasmic reticulum (nSR). By contrast, we find no evidence of similar nSR labeling for other SERCA or RyR. It seems likely, therefore, that a variety of calcium pumps and release channels, with different kinetics and affinities for calcium, are strategically positioned within and serve to demarcate different nanojunctions of the SR and their respective cytoplasmic nanodomains. Function-specific calcium signals may thus arise to provide for selective modulation of smooth muscle contraction and gene expression.

Targeted STIM deletion impairs calcium homeostasis, NFAT activation, and growth of smooth muscle cells

S. Mancarella, S. Potireddy, Y. Wang, H. Gao, R. Gandhirajan, M. Autieri, R. Scalia, H. Wang, M. Madesh, S. Houser and D. Gill

Temple University School of Medicine, Philadelphia, PA, USA

Stromal interaction molecule (STIM1) and its isoform (STIM2) are single span sarco/endoplasmic (SR) transmembrane proteins that function as powerful SR Ca2+ sensors. When the SR Ca2+ content decreases STIM proteins migrate in proximity of the plasma membrane to tether and activate the Orai channels initiating the so called store operated Ca2+ entry (SOCE). In non-excitable cells STIM mediates Ca2+ entry that is required for regulating cell proliferation and migration. Smooth muscle cells (SMC) can exist as non-excitable cells, known also as the “proliferative” phenotype, or as excitable cells, known as the “contractile” phenotype. Furthermore, SMC can interchange their phenotype in response to environmental stimuli; Ca2+ signaling plays a crucial role in regulating this transition. However, very little is known about the role of STIM in SMC. Because isolated primary SMC quickly lose their contractile phenotype when placed in culture, the role of STIM proteins in SMC has been eluded. To overcome this limitation we used the Cre-lox technology approach to generate SM-specific STIM1-, STIM2-, and STIM1/STIM2- knockout (KO) mice, this model allowed us to systematically analyze the physiological role of STIM in SMC.

SM-STIM1-KO mice survival rate was only about 50% within the first 30 days after birth. In addition, SM-STIM1-KO mice showed

a consistent reduced body weight when compared to control mice. While the SM-STIM1/STIM2 double-KO phenotype was perinatally lethal, the SM-STIM2-KO was without a detectable phenotype. However, in the SM-STIM1 KO mice the STIM2 expression is enough to rescue the otherwise lethal phenotype, revealing that also STIM2 plays an important role in the SMC. Smooth muscle containing organs, such as intestine and aorta harvested from SM-STIM1-KO mice revealed morphological abnormalities when compared with organs harvested from control mice. Vascular reactivity analyzed using wire myography revealed that while depolarization-induced aortic contraction was unchanged, phenylephrine-mediated contraction was reduced by 26%, and store-dependent contraction was almost eliminated in aortas isolated from SM-STIM1-KO mice. Neointima formation induced by partial carotid artery ligation was suppressed by 54%. Consistently, in vitro PDGF-induced SMC proliferation was also reduced by 79% in STIM1-KO SMC. Notably, the Ca2+ store-refilling rate in STIM1-KO SMCs was substantially reduced, and sustained PDGF-induced Ca2+ entry was abolished. This defective Ca2+ homeostasis prevents PDGF-induced NFAT activation in both contractile and proliferating SMCs. In conclusion, our data show that STIM1-regulated Ca2+ homeostasis is crucial for NFAT-mediated transcriptional control required for induction of SMC proliferation, development, and growth during physiological as well as pathophysiological conditions.

NFAT-dependent excitation-transcription coupling in smooth muscle

M.F. Gomez

Lund University, Malmö, Sweden

Patients with diabetes have a much more widespread and aggressive form of atherosclerosis in the coronary arteries, lower extremities and extracranial carotid arteries, causing nearly 80% of all deaths and much of the disability in these patients (1). Diabetes type 1 and 2 are independent risk factors for myocardial infarction, peripheral vascular disease and stroke, also worsening their early and late outcomes, increasing the risk of recurrence and leading to poorer prognosis following surgical revascularization procedures. Despite the vast clinical experience linking diabetes and atherosclerosis, very little is understood about the molecular mechanisms connecting hyperglycemia to atherosclerosis.

The nuclear factor of activated T-cells (NFATc1-c4) are a family of Ca^{2+}/calcineurin-dependent transcription factors first characterized in T-lymphocytes as inducers of cytokine gene expression. Since then, NFAT proteins have been shown to play various roles outside immune cells, including in the cardiovascular system (2). We have previously shown that modest elevations of extracellular glucose effectively activate NFATc3 in vascular smooth muscle cells (VSMC) of large arteries (aorta and cerebral) and in small (retinal) microvessels in mice, both *ex vivo* and *in vivo* (3; 4). This effect involves the local release of extracellular nucleotides, such as UTP and UDP, acting on purinergic-2Y receptors, leading to increased $[Ca^{2+}]_i$ and subsequent activation of calcineurin and NFATc3. In addition to promoting NFATc3 nuclear translocation, high glucose also reduces nuclear export of NFAT by inhibiting GSK-3β and JNK, providing additional mechanisms for glucose-induced NFAT activation. Once activated, NFAT promotes the expression of osteopontin (OPN). Diabetic mice showed increased expression of OPN in the ascending and thoracic aorta, vascular segments particularly prone to development of atherosclerosis and this was prevented by *in vivo* treatment with the NFAT inhibitor A-285222 or by lack of NFATc3 protein in arteries from $NFATc3^{-/-}$ mice. Additional experimental evidence supports a role for NFAT as a regulator of genes able to promote vascular dysfunction and potentially, a pro-atherogenic vascular phenotype. NFAT promotes VSMC proliferation and migration, and plays a role in neointima formation and in the regulation of cyclooxygenase 2 (Cox2) and RCAN1 expression after vascular injury (5). NFAT contributes to the development of angiotensin II-induced hypertension, via down-regulation of potassium channel expression (6). Moreover, NFAT controls the alternative splicing of allograft inflammatory factor-1 (AIF-1), resulting in products differentially associated to parameters defining human plaque phenotype and stability (7).

Together, these observations led us to hypothesize that NFAT may act as a glucose-sensor in the vessel wall, translating changes in Ca^{2+} signals into changes in gene expression that lead to macrovascular disease in diabetes. To more directly test this hypothesis and in the context of an atherosclerosis-prone experimental model, we investigate the effects of NFAT-signaling inhibition on atherosclerotic plaque formation and inflammatory burden in diabetic and non-diabetic apolipoprotein (Apo)E deficient mice. We found that inhibition of NFAT-signaling completely suppresses the diabetes-induced aggravation of atherosclerosis, also effectively reducing the expression of OPN, MCP-1, IL-6, ICAM-1 and tissue factor in the arterial wall. This effect was independent of changes in plasma glucose or lipid levels, and not due to systemic immunosuppression. These findings suggest that NFAT may play a role in the development of atherosclerosis in diabetes and identifies this signaling pathway as a novel therapeutic target for the treatment of diabetic macrovascular complications.

Has the continuing relevance of comparative physiology "gone missing" in biomedical research?

M.J. Joyner

Anesthesiology, Mayo Clinic, Rochester, MN, USA

Biomedical research relies on limited animal models to address questions related to human health. The limitations of inbred or genetically modified rodent models has become especially clear recently based on a number of high profile publications showing limited animal to human translation. Historically, many key discoveries have been generated by studies on a range of animals adapted to unusual environments. For example major advances in the understanding of the microcirculation continue to come from studies of the bat wing. In this context, the goal of this symposium is to explore what might be described as the "re-emergence" of comparative physiology to address important questions in human health and disease. It will also highlight sex differences in blood pressure regulation in humans.
This talk will provide a brief historical overview of the issues outlined above and also highlight areas such as hypoxia tolerance, and maintenance of bone and muscle mass during extreme inactivity where there are comparative "solutions" to problems with high relevance to human health and disease.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Sex, nerves and blood pressure: a comparative analysis of the role that sex plays in blood pressure modulation

E.C. Hart[1], N. Charkoudian[2], G. Wallin[4] and M. Joyner[3]

[1]Physiology and Pharmacology, University of Bristol, Bristol, UK, [2]US Army Research Institute of Environmental Medicine, Natick, MA, USA, [3]Mayo Clinic and Foundation, Rochester, MN, USA and [4]Institute of Neuroscience and Physiology, University of Goteborg, Goteborg, Sweden

Sex hormones are essential in the development of the biological and physiological sexual characteristics of males and females. However, it is well known that they also play an important role in modulating cardiovascular regulation, particularly with regard to regulation of arterial pressure. Recent comparative examinations of blood pressure regulation in healthy men and women have increased our understanding regarding normal blood pressure control and how sex /sex hormones might influence the development of cardiovascular diseases such as hypertension. Previous studies have shown that, under the age of 40, men and women do indeed regulate resting blood pressure differently. The sympathetic nervous system is central to blood pressure regulation in humans; despite this, basal levels of muscle sympathetic activity (MSNA, an estimate of central sympathetic outflow) are not related to resting blood pressure in either men or women. How can this be when MSNA causes vasoconstrictor tone? Interestingly, in young men MSNA is positively related to peripheral vascular resistance but inversely related to cardiac output. Consequently, men with high MSNA have a high vascular resistance but a lower cardiac output. This balance negates the effect of MSNA on resting blood pressure in men; so men with high MSNA can have a normal resting blood pressure. However, this balance does not exist in young women. In young pre-menopausal women, MSNA is not related to total peripheral resistance or cardiac output. Thus, it appears that basal levels of MSNA contribute little to resting peripheral vasoconstrictor tone. Importantly, this difference between men and women appears to change with age and menopausal status. In postmenopausal women, MSNA becomes directly related to peripheral vascular resistance and blood pressure. This provides strong evidence that sex and sex hormones might modulate how MSNA affects resting blood pressure.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Maintaining homeostasis despite deadly physiological extremes: lessons from a natural expert

S. Martin[1,2], A. Hindle[1] and K. Grabek[1,2]

[1]Department of Cell and Developmental Biology, University of Colorado School of Medicine, Aurora, CO, USA and [2]Human Medical Genetics and Genomics Program, Univ of Colorado School of Medicine, Aurora, CO, USA

Hibernating ground squirrels survive physiological deviations so removed from the mammalian norm that they inevitably lead to death in non-hibernators. In 13-lined ground squirrels and other circannual, or obligate, hibernators, a season of homeothermy that begins with reproduction and ends with obesity is segregated from a season of hibernation. Hibernation is characterized by cycles between extended (~2 weeks) bouts of torpor, punctuated by short (12 hr) arousals to typical euthermic conditions that are superimposed upon months of continuous fasting and inactivity. In torpor, the hibernating mammal exhibits profound drops in heart rate from a few hundred to a few beats/min, metabolic rate to a few percent of active, and core body temperature from 37°C to near zero. Remarkably, the physiological depressions are spontaneously reversed without harm during each arousal. Moreover, at the end of hibernation, the animal returns to homeothermy with surprisingly little muscle, gut or bone disuse atrophy. Clearly, numerous features of the hibernation phenotype would be beneficial if they could be harnessed and applied to humans. Because superimposition of hibernating species on the mammalian phylogeny implies that the common ancestor of all mammals was a hibernator (6), the possibility of deriving useful therapies that mimic various aspects of the hibernation phenotype is within the realm of science, and not merely science fiction. The first step towards achieving this goal is to define the molecular pathways and mechanisms used during natural hibernation to orchestrate and manage their remarkable phenotypic plasticity. Because hibernation's varied phenotypes are so distinctive, it is unlikely that hypothesis-driven work based on understanding of non-hibernators will provide the transformative data needed to understand hibernation at a molecular level. Our approach to this problem is to interrogate a precisely timed set of samples from 13-lined ground squirrels representing hibernation's major physiological phenotypes for biochemical differences. Our working hypothesis is that hibernation is a cycle-within-a-cycle, with the torpor-arousal cycles being embedded within a summer-winter seasonal cycle. This model predicts a resetting of baseline physiology between the summer and winter modes that leads to tissue protection and that it is only in the protected winter

state that torpor can be elicited. To test the predictions of this hypothesis and identify the underlying molecular mechanisms, we have collected an extensive tissue bank representing multiple timepoints throughout the year that represent key transitions in both cycles together. These samples are being examined with high-throughput 'omics' methodologies to identify the metabolites, proteins and transcripts in multiple organs that are candidates to support and drive the remarkable physiological transitions of hibernation. Early data support our model of an altered baseline physiology that separates winter from summer animals and reveal a surprising degree of tissue-specific variation that reflects unique aspects of organ function in the changes observed (1-5).

Comparative physiology in regenerative medicine

H. Lauridsen

MR-Research Centre, The Institute of Clinical Medicine, Aarhus University, Aarhus N, Denmark

Advances in stem cell research and tissue engineering in recent decades have led, i.a., to the generation of induced pluripotent stem cells and biocompatible artificial scaffolds, inspiring hope for future regenerative therapies. Progress in the field of regenerative medicine is, however, inevitably difficult applying the mammalian model organisms traditionally used in biomedical research, owing to the lack of tissue regenerative potential in these organisms. In contrast, urodele amphibians possess impressive regenerative capabilities at both tissue, organ, and structural level, and are apt models for regenerative biology and medicine, exemplified in the iconic Mexican axolotl (Ambystoma mexicanum). In this talk I will present the axolotl as an important comparative model for unraveling the mechanisms of intrinsic tissue regeneration in general and in particular as a model for tissue regeneration following myocardial infarction as well as a model for stem cell tracking using MRI for non-invasive evaluation of future regenerative therapies.

The axolotl heart has been described to recover completely following partial ventricular amputation of the apex, serving as a model for regeneration in a relatively simple structure in the sense of only a few different tissues involved. Removal of heart tissue in the form of partial amputation is, however, not a very clinically relevant situation, on the other hand regeneration following myocardial infarction is highly clinically relevant. We have developed an axolotl myocardial infarction model that allows for description and discovery of regenerative events in the process of heart repair. In this talk I will present our latest discoveries of basic molecular and cellular mechanism that are activated at the initiation of heart regeneration in the axolotl.

One fundamental challenge of future stem cell therapies will be the ability to monitor the progress of therapy in the sense of being able to track injected stem cell. The technique to accomplish this has to be non-invasive - there is no point in regenerating tissue, if this is destroyed by biopsies later on to ensure that regeneration has in fact taken place. Additionally, cell tracking technology will have to be safe and repetitive to allow for follow up evaluations. Ultrasmall superparamagnetic iron oxide particles (USPIO), nanoparticles containing an iron oxide core and a biocompatible coating, have been suggested and applied for non-invasive and safe stem cell tracking in preclinical studies, as cells labeled with these particles can be detected with MRI due to their ferrous core. We have developed a fluorophore conjugated USPIO detectable with MRI and optical imaging and tested the tracking methodology in the axolotl, in this situation serving as a model of intrinsic regeneration.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Comparative physiology of temperature regulation: of brains and different sized bodies

S.K. Maloney[1], A. Fuller[2] and D. Mitchell[2]

[1]Anatomy Physiology and Human Biology, University of Western Australia, Crawley, WA, Australia and [2]Physiology, University of the Witwatersrand, Johannesburg, Gauteng, South Africa

We discuss the relevance of comparative physiology to aspects of temperature regulation, and the problems of extrapolating from animal models to humans. Students of comparative physiology learn detail of size scaling laws in animal energetics, including laws that describe the effect of body size on heat exchange and on the thermoneutral zone. Much of the research on animal models of human disease, including genetic risk models, is done on rodents maintained at 22-23°C, a temperature well below a rodent's thermoneutral zone. In some disease domains this experimental anomaly may not matter, but the increase in metabolism and decrease in RQ (indicative of increased fat oxidation) that occurs below the thermoneutral zone may confound extrapolations to humans in any disease with a metabolic component. Another medical issue topical currently is whether isolated cooling of the traumatized human brain is feasible, the study of which is confounded by the difficulty of measuring deep brain temperature in healthy humans. Based on studies of many other species, we show that capacity for selective brain cooling depends on the carotid rete, a structure that humans and other

primates do not possess, rendering it improbable that humans can implement selective brain cooling. The primary determinant of brain temperature is the temperature of the blood reaching it. If the temperature of blood destined for the brain is manipulated, isolated cooling of the brain is possible. Cooling the head without cooling the blood destined for the brain does not result in isolated brain cooling.

Role of myocardial reactive oxygen species (ROS) signalling in post-operative and non-surgical atrial fibrillation

B. Casadei

University of Oxford, Oxford, UK

Atrial fibrillation (AF) is common and is associated with significantly increased morbidity and mortality (mostly due to heart failure and stroke). A striking feature of AF is the ability of this arrhythmia to sustain itself. It is accepted that, by increasing atrial rate, AF leads to electrical and structural remodelling of the atria, which, in turn, promotes AF maintenance and increases vulnerability to relapse. There is considerable interest in developing treatment and prevention strategies that target mechanisms upstream of ion channels modifications (e.g., myocardial redox state and metabolism); however, whereas changes in ion channels conductance are the common denominator of virtually all types of AF, the myocardial signalling upstream of atrial electrical and structural remodelling may differ with the stage and substrate of AF, demanding a more refined ad hoc approach to the prevention and management of this arrhythmia. For example, we have shown that a gp91phox-containing NADPH oxidase (NOX2) is the main source of reactive oxygen species (ROS) in human atrial myocytes, and that atrial NOX2 activity is independently associated with an increased risk of developing AF and other postoperative complications in patients undergoing cardiac surgery. We have also established that short term treatment (3 days) or ex vivo tissue incubation with HMG CoA reductase inhibitors (statins) increases NO bioavailability and reduces vascular and cardiac NOX2 activity in patients undergoing coronary revascularization by inhibiting one of the key components of the oxidase complex (i.e., the small G protein Rac1), before any change in LDL cholesterol can be detected. Together, these findings suggest that NOX2 inhibition with statins may help prevent the new onset of AF after cardiac surgery and, possibly, in other disease states characterized by inflammation. However, whether NOX2 inhibition may also be beneficial in the secondary prevention of AF or in conditions where atrial structural remodeling provides the arrhythmic substrate remains a matter of debate. To address this issue, we investigated the time-dependent changes in the expression and activity of atrial oxidase systems in the atrial myocardium of goats with pacing-induced AF (2 weeks and 6 months) or atrial structural remodeling secondary to atrioventricular block, and in human atrial samples. We found that NOX2 and Rac1 activity and the protein level of the cytochrome-forming subunits of the oxidase (NOX2 and p22phox) are significantly increased in the left atrial myocardium of goats after 2 weeks of AF and in atrial samples from patients in sinus rhythm who develop AF after cardiac surgery. By contrast, the increase in ROS production observed in longstanding AF or in the presence of atrioventricular block (i.e., in the presence of atrial structural remodeling) is due to mitochondrial oxidases and NOS "uncoupling" (a phenomenon whereby the catalytic electron flow within the enzyme is uncoupled from NO synthesis and diverted to molecular oxygen to yield superoxide), secondary to a reduction in the atrial content of the NOS co-factor BH4 and an increase in arginase activity.
Ex vivo atorvastatin causes a mevalonate-reversible inhibition of atrial Rac1 and NOX2 activity in patients who develop AF after cardiac surgery, but it does not affect atrial ROS production, NOS uncoupling or BH4 content in patients with permanent AF.
Taken together, these data demonstrate that the mechanisms responsible for the NO-redox imbalance in the fibrillating atrial myocardium change with the duration of AF and the development of atrial structural remodeling and suggest that a shift in the atrial sources of ROS with the duration of AF may influence the antiarrhythmic efficacy of statins.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Changes in spatio-temporal pattern of Ca2+ release in tachycardia-induced atrial remodelling

M. Greiser[1,2] and U. Schotten[1]

[1]Maastricht University, Maastricht, Netherlands and [2]University of Maryland, Baltimore, MD, USA

Atrial fibrillation (AF) is characterized by sustained high atrial activation rates and cellular Ca2+ signaling instability, which is thought to contribute to atrial arrhythmogenesis. How high rate and arrhythmogenic Ca2+ instability may be related, however, is poorly understood. We have characterized the effect of sustained high atrial activation rates on sub-cellular Ca2+ signaling in a rabbit model. L-type Ca2+ current and whole cell [Ca2+]i transient were reduced as was ryanodine receptor (RyR2) expression (by 77%) with a 7fold increase in RyR2 phosphorylation (Ser2809). Ca2+ release in the myocyte center was blunted due to increased [Ca2+] buffering strength. The spatial distribution of junctional and central SR sites was unchanged. Surprisingly, SR Ca2+ content, characteristics and rates of Ca2+ sparks and -waves were unchanged. Computational estimates of Ca2+ signaling suggest that the observed behavior arises from a higher Ca2+ leak rate per RyR2 associated with less RyR2s per SR cluster. Additionally, lower total Ca2+ release per [Ca2+]i transient, due to failed Ca2+ wave propagation to the myocyte center and the higher Ca2+ buffering strength contribute. Sustained high atrial rates produce "Ca2+ signaling silencing" and not Ca2+ instability. Ca2+ signaling silencing serves as an adaptive response to rapid myocyte activation and this hampers the development of Ca2+ dysregulation-based arrhythmogenic mechanisms

Chasing tails: clinics and C-termini

F. Karet

University of Cambridge, Cambridge, UK

It is well recognized that the C-terminal domains of many proteins are important for directing them to heir correct cellular destination. Molecular genetic and cellular investigations of patients with a variety of inherited conditions that result from trafficking and targeting abnormalities have provided insights into the normal behaviour of membrane and other compartment residents.
This talk will illustrate a range of such mechanisms that are of particular importance in the kidney, set in the context of a specialist multidisciplinary clinical service.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

The role of Tmem27 and ACE2 on renal neutral amino acid transport

S.M. Camargo

University of Zurich, Zurich, ZH, Switzerland

The interaction of amino acid transporters with accessory proteins guarantees their insertion in the membrane and may modulate the activity or the supply of substrate. Neutral amino acid transporters of the SLC6 family have been shown to rely on the expression of Tmem27 and the angiotensin-converting enzyme 2 (ACE2), two members of the renin-angiotensin system (RAS). ACE2 and Tmem27's role as a partner protein of amino acid transporters was revealed by gene ablation and co-expression in heterologous system. The *tmem27* knock-out mice presented generalized neutral aminoaciduria, while *ace2* knock-out animal had normal amino acids excretion. The amino acid transport in the kidneys of *tmem27* and intestine of *ace2* knock-out animals is reduced, moreover Slc6 family amino acid transporters expression is affected. In the kidney of *tmem27* mice the expression of B^0AT1, B^0AT3 (*Slc6a19* and *18*) and the imino transporter SIT1 (*Slc6a20*) were abolished or strongly reduced. In the *ace2* knock-out mice the renal expression of B^0AT1 was normal, while it was absent in the small intestine. B^0AT1 is the major neutral amino acid transporter in the kidney and intestine, and has two tissue specific accessory proteins, Tmem27 in the kidney and ACE2 in intestine. Mutations in the gene (*SLC6A19*) encoding the B^0AT1, but not in the genes encoding the accessory proteins, are the cause of Hartnup disorder. Hartnup disorder patients present aminoaciduria, and may also additionally develop symptoms resembling pellagra, including light-sensitive dermatitis and diarrhea that manifests under conditions of stress and malnutrition. Pellagra like symptoms is thought to result from defective intestinal absorption of L-tryptophan, the precursor of niacin. The ablation of B^0AT1 in the intestine of *ace2* knock-out mice leads to a decreased L-tryptophan absorption, increased susceptibility to intestinal infection, but not to dermatitis-like symptoms. These results suggest that B^0AT1 ablation in intestine may contribute to the development of symptoms different from aminoaciduria observed in the Hartnup disorder subjects. The phenotype of Hartnup patients has been shown to vary due to nutritional status, environment, and high frequency of compound heterozygous. Additionally, mutated transporter can interact differentially with tissue specific accessory proteins, and might contribute to the phenotypic heterogeneity among individuals with Hartnup disorder. The work on amino acid transporters of the SLC6 family and their tissue-specific partner proteins has provided critical information concerning the modulation of amino acid transporter function, however several questions are still waiting to be solved such as the mechanism guiding the selection of the partner protein in kidney, regulation of the expression and function of the transporters and their accessory proteins by diet, gender, hormones, age and diseases are crucial and are just starting to be investigated.

Disorders of neutral amino acid transport

S. Broer

Research School of Biology, Australian National University, Canberra, ACT, Australia

The proximal tubule is endowed with a variety of neutral amino acid transporters to ensure efficient reabsorption of this large group of metabolites. Molecular cloning efforts have successfully identified apical transporters for amino acids. The major transporter for neutral amino acids (SLC6A19 or B0AT1) mediates the uptake of all neutral amino acids. Mutations in this transporter cause Hartnup disorder. Surface expression of B0AT1 requires expression of collectrin (TMEM27) in the kidney or of angiotensin converting enzyme 2 in the intestine. Complete reabsorption of proline and glycine requires additional transporters, namely SLC6A20 (SIT1) and SLC36A2 (PAT2). Mutations in these transporters cause iminoglycinuria and glycinuria, two benign aminoacidurias, which are however interesting from a genetic point of view. Combination of different alleles can cause similar phenotypes in homozygotes,

but present differently in heterozygotes. In mice neutral amino acid reabsorption is different from humans making use of SLC6A18 (B0AT3) instead of PAT2. Human SLC6A18 is an inactive protein, which is still expressed in the proximal tubule but does not appear to have a functional role. B0AT3 also requires collectrin or ACE2 for surface expression, but its expression mainly overlaps with collectrin. A mouse model lacking SLC6A19 in the intestine and kidney shows reduced body weight and cannot control body weight on diets of different protein content. On a high-fat diet the animals gain less weight than wild-type litter mates. Insulin sensitivity and glucose tolerance are improved compared to wildtype mice. The mechanisms underlying these physiological changes are currently under investigation.

Tubular defects leading to renal stones

J.A. Sayer

Institute of Genetic Medicine, University of Newcastle, Newcastle upon Tyne, UK

Renal stone disease may be seen as clinical symptom of an underlying pathological process predisposing to crystallization within the renal tract.
Molecular genetics has allowed significant progress to be made in our understanding of renal tubular salt handling which underlies certain stone forming conditions. The molecular defect underlying these inherited tubular disorders often contributes to a significant metabolic risk factor for stone formation. In contrast, idiopathic renal stone formation relates to the interplay of environmental, dietary and genetic factors, with hypercalciuria being the most commonly found metabolic risk factor. The pathophysiological and genetic basis underlying familial hypercalciuria and calcium stone formation remains elusive.
Here I will discuss known molecular players in the pathogenesis of hypercalciuria and the need for novel insights into why the majority of hypercalciuria remains unexplained

Uromodulin-associated kidney diseases

O. Devuyst

Institute of Physiology, University of Zürich, Zürich, Switzerland

Uromodulin (Tamm-Horsfall protein) is the most abundant protein excreted in the urine under physiological conditions. It is exclusively produced in the kidney and secreted into the urine via proteolytic cleavage. Its biological function is still not fully understood. Uromodulin has been linked to water/electrolyte balance and to kidney innate immunity. Studies in knockout mice demonstrated that it has a protective role against urinary tract infections and renal stone formation. Mutations in the *UMOD* gene encoding uromodulin lead to rare autosomal dominant diseases, collectively referred to as uromodulin-associated kidney diseases. They are characterized by progressive tubulointerstitial damage, impaired urinary concentrating ability, hyperuricemia, renal cysts, and progressive renal failure. Novel in vivo studies point at intracellular accumulation of mutant uromodulin as a key primary event in the disease pathogenesis. Recently, genome-wide association studies identified uromodulin as a risk factor for chronic kidney disease (CKD) and hypertension, and suggested that the level of uromodulin in the urine could represent a useful biomarker for the development of CKD. These investigations emphasize the scientific and clinical interest for this long discovered molecule.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Translational spectral electroencephalographic markers in the European PharmaCog project: a new resource for drug discovery for Alzheimer's disease

C. Babiloni[1,2], F. Infarinato[3], J.F. Bastlund[4], B. Clausen[4], G. Forloni[5], A. Frasca[5], M. Bentivoglio[6], P.F. Fabene[6], G. Bertini[6], J. Kelley[7], S. Dix[8], J.C. Richardson[9], W. Drinkenburg[7] and C. Del Percio[3]

[1]University Sapienza, Rome, Rome, Italy, [2]University of Foggia, Foggia, Italy, [3]IRCCS San Raffaele Pisana, Roma, Italy, [4]Lundbeck, Valby, Denmark, [5]Mario Negri Institute, Milano, Italy, [6]University of Verona, Verona, Italy, [7]Janssen, Beerse, Belgium, [8]Eli Lilly, Basingstoke, UK and [9]GSK, Brentford, UK

In the IMI PharmaCog project (2010-2014) we showed that the electroencephalographic (EEG) rhythms related to eyes opening as a condition of cortical arousal are abnormal in patients with mild cognitive impairment and Alzheimer's disease (AD; Babiloni et al., 2010, JAD). Towards a back-translation we evaluated whether EEG rhythms related to motor activity change across physiological aging in wild type (WT) mice, as well as in Tg models of AD such as PDAPP and TASTPM mice. For the physiological aging, EEG data were recorded in 19 young (4.5-6 months), 12 middle age (12-14 months), and 15 old (24 months) male WT mice. For the pathological aging, EEG data were recorded in 15 WT vs. 10 PDAPP male mice (24

months), as well as in 14 WT mice (12-14 months) vs. 15 TASTPM mice (12-14 months). Artifact-free EEG segments during wake active state (gross movements, exploratory movements or locomotor activity) and passive state (no sleep) were used as an input for EEG power density analysis. Results showed that (1) 1-2 and 2-4 Hz power density during the passive state was greater in old WT than in young and middle age WT mice ($p<0.05$); (2) 6-8 Hz power density during the active state was greater in these old mice ($p<0.05$); (3) 8-10 Hz power density during the active state was greater in young than in middle age mice ($p<0.05$); (4) 2-4 and 4-6 Hz power density during the passive state was lower in PDAPP compared to WT mice ($p<0.05$); (5) 8-10 Hz power density during the active state was lower in PDAPP compared to WT mice ($p<0.05$); (6) 2-4 and 4-6 Hz power density during the passive state was lower in TASTPM compared to WT mice ($p<0.05$); and (7) 10-12 Hz power density during the active state was lower in TASTPM compared to WT mice ($p<0.05$). The present results suggest that the EEG markers of motor activity are useful to unveil neurophysiological mechanisms of cortical neural synchronization characterizing the physiological aging in WT mice, as well as the pathological cortical neural synchronization in Tg mice.

Cortical gamma oscillations and mitochondrial dysfunction: food for thought in neurodegeneration?

M.O. Cunningham

Institute of Neuroscience, The Medical School, University of Newcastle upon Tyne, Newcastle Upon Tyne, UK

Mitochondria are a cell organelle responsible for the production of energy for cellular activities. This is done mainly by the formation of ATP through oxidative phosphorylation via the mitochondrial respiratory chain. Since neurons are highly active cells, it is not surprising that neurons depends highly on optimal mitochondrial function for their survival and a broad range of physiological activities. Increasingly, neurodegenerative disorders are being identified as having secondary mitochondrial dysfunction. These include Alzheimer's disease (AD), Parkinson's disease (PD) and Huntington's disease (HD). In all of these conditions, cognitive dysfunction is a core symptom with limited effective nootropic therapies currently available.

In attempting to understand the role of mitochondrial dysfunction and the implications of this for cognitive processes we have utilized in vitro brain slice preparations. Using this technique, patterns of cortical network activity associated with cognitive processes can be reproduced. In particular, we have examined oscillatory activity in the range of 30-80 Hz, termed the gamma frequency oscillation. This approach also affords sufficient access and manipulation to probe their network, cellular and synaptic underpinnings.

Using this approach, data from studies using rodent and human brain slices will be presented which illustrate that the cortical gamma frequency oscillation depends largely on mitochondrial energy formation and highly sensitive to mitochondrial dysfunction, especially complex I inhibition1. We will also provide evidence that within this context, our results suggest that the decline in gamma oscillation power seen with inhibitors of the mitochondrial respiratory chain results primarily from effects on these fast spiking interneurons.

These findings may offer insight into pathophysiology of cortical dysfunction in neurodegenerative conditions in which secondary mitochondrial dysfunction is implicated.

Neuron-glia crosstalk under pathological condition of Alzheimer's disease

I. Mook-Jung

Biochemistry & Biomedical Sciences, Seoul National University College of Medicine, Seoul, Republic of Korea

Alzheimer's disease (AD) is a progressive and irreversible neurodegenerative disorder that leads to cognitive dysfunction, memory impairment and emotional disturbance in elderly persons. Activated microglia and reactive astrocytes are commonly found in and around the senile plaques that are the central pathological hallmark of AD. Beta-amyloid peptide (Abeta) accumulates in these plaques. Astrocytes respond to neuronal activity through the release of gliotransmitters such as glutamate, d-serine and adenosine 5'-triphosphate (ATP). How gliotransmitters regulate neuronal activity, however, is not well defined and even controversial. Also, astrocyte secreted several proteins to the synapse, which modulate synaptic function including synaptogenesis and neurogenesis directly or indirectly to the neurons. In the present study, we examined the effect of one of gliotransmiitters, ATP on neurons damaged by Abeta42 peptides in both primary astrocytes and U373 astrocyte cell line. We found that exogenous ATP protects against Abeta42-mediated reduction in synaptic molecules, such as NMDA receptor 2A, PSD-9ATP5 and synaptophysin, through purinergic receptor P2X in primary hippocampal neurons. ATP also prevented Abeta42-induced spine reduction and impaired long-term potentiation in the hippocampal neurons. Our findings suggest that Abeta-induced gliotransmitter ATP plays a protective role against Abeta42-mediated synaptic plasticity disruption. As an astrocyte-secreted protein, thrombospondin-1 (TSP-1) was examined in vitro and in AD animal model (5XFAD mice). The release of TSP-1 from astrocytes was decreased by Abeta42 in vitro, and the reduced level of TSP-1 was observed in brains of AD animal models. Synaptic pathology caused by Abeta42 such as decreased dendritic density, impaired synaptic activity, and reduced long-term potentiation (LTP) were prevented by co-incubation with TSP-1 and

Abeta. TSP-1 is a potential therapeutic component against the damaging effects caused by Abeta42 in AD pathogenesis.

Understanding physiological roles of microtuble binding protein tau

D. Whitcomb

University of Bristol, Bristol, Bristol, UK

Tau is a microtubule binding protein and has been identified as a key molecule in Alzheimer's disease (AD), as well as other tauopathies (Ballatore et al., 2007). Though tau is primarily located in axons, the entirety of its physiological roles are yet to be clearly defined. Given the dysregulation of the synapse in AD pathology (Selkoe, 2002), we investigated a possible physiological synaptic function of tau. We studied synaptic plasticity in the rat hippocampus, and found a selective deficit in long-term depression (LTD) as a result of RNAi knockdown of tau in vitro. Furthermore, we found that the induction of LTD is associated with the phosphorylation of tau, and this is required for the activation of key AMPA receptor internalisation mechanisms. These findings demonstrate that tau has a critical function in AMPA receptor trafficking during LTD and suggest that tauopathies may result from an aberrant form of LTD in the CNS.

Gender specific differences in muscle protein metabolism

B. Mittendorfer

Geriatrics And Nutritional Sciences, Washington University School of Medicine, St Louis, MO, USA

Sexual dimorphism in body composition and muscle mass is well recognized. The mechanisms responsible for this phenomenon and how a person's sex affects the response to anabolic and catabolic stimuli are not completely understood. Several studies indicate that there is no difference in the basal rate of muscle protein synthesis or muscle protein breakdown or the anabolic responses to nutritional stimuli and resistance exercise in young and middle-aged adult men and women. Nevertheless, recent evidence suggests that aging affects muscle protein turnover differently in men and women. The basal rate of muscle protein synthesis is greater in old women than in old men; in addition, both old women and old men are resistant to the anabolic effects of exercise and nutrition and old women appear to be more resistant than old men. This suggests that differences in muscle protein turnover between men and women might be most apparent when muscle mass is changing (i.e., during aging vs. young and middle-adulthood when muscle mass is steady) and suggests a possible role of changes in the hormonal milieu with aging, in particular at the onset of menopause in women.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA422

Metabolic and molecular regulation of skeletal muscle in older age

P.J. Atherton

School of Graduate Entry Medicine and Health, University of Nottingham, Derby, UK

Physical activity in the form of exercise or increasing the plasma availability of essential amino acids (EAA) by exogenous supply (orally or intravenously) or via oral protein sources stimulates skeletal muscle anabolism. Mechanistically, EAA-induced increases in muscle protein synthesis (MPS) are initiated after AA-transportation into the muscle cell whereupon leucine indirectly activates the mechanistic target of rapamycin complex-1 (mTORc1), independent of proximal insulin signaling (phosphatidylinositol 3-kinase (PI3K)) pathways. Similarly, exercise also stimulates mTORc1 signaling via mechano-mediated routes, again largely independent of proximal insulin signalling. Subsequent downstream mTORc1 signaling enhances translational initiation via activation of mTORc1 substrates (e.g. p70S6K1, 4EBP1) culminating in ribosomal assembly, polyribosome formation and increased MPS. In terms of kinetics, skeletal muscles are receptive to the anabolic effects of EAA for only a short period, equating to ~2 h in the rested state (even after ~50 g EAA-rich protein), thereafter becoming refractory despite continued EAA availability and mTORc1 signalling. This phenomenon has been termed "muscle-full", whereby muscles intrinsically sense "excess" EAA and divert them toward oxidation. Episodes of physical activity (i.e., exercise) are able to delay the "muscle-full" signal to facilitate muscle adaptation (e.g. cellular remodelling/ hypertrophy) in accordance to the demands of the exercise activity imposed e.g. resistance vs. endurance. Intake of nutrition also provides a second route for muscle anabolism via suppression of muscle protein breakdown (MPB). This occurs independently to direct effects of EAA on MPB since EAA supply under insulin clamped conditions (postabsorptive ~5μU.ml-1) is insufficient to suppress MPB. Instead, the release of insulin in response to nutrition causes suppression of MPB (~15μU.ml-1 provides ~50% suppression). On this basis, the robust insulin secretagogue properties of EAA are likely sufficient to increase plasma insulin enough to supress MPB, and maximise nutrient-driven muscle anabolism even in the absence of carbohydrates. To facilitate delivery of AA and insulin to the myocellular-capillary interface, nutrients also modulate peripheral vascular function. Indeed, while insulin is known to increase blood flow to skeletal muscle, certain AA (e.g. arginine, the precursor for nitric

oxide) can also enhance muscle microvascular flow. Therefore, an appreciation of the co-ordination between endocrine pancreas, peripheral vasculature, and muscle cells is needed to understand the anabolic effects of AA and the nature of any interactions with exercise in terms of muscle protein anabolism. In terms of ageing, it has been demonstrated that the transient anabolic effects of exercise and/or EAA are blunted in older age (vs. younger groups) providing evidence for the existence of so-called 'anabolic resistance'. While this phenomenon has been proven in both pre-clinical and clinical scenarios as an "all-cause" mechanism of skeletal muscle atrophy, how much this relates to inactivity in older-aged individuals remains to be definitively determined. Nevertheless, this has lead to suggestion that strategies aimed at increasing dietary EAA-intake or enhancing the anabolic effects of exercise/nutrition represent important foci in treating sarcopenia. To summarise, optimal nutritional strategies for older individuals need to be viewed in the context of the gut-vascular-pancreas-muscle axis and in terms of interactions with physical activity; only comprehension of all these facets will afford full exploitation of the anabolic efficacy of nutrition and exercise in sarcopenia. Finally, a better comprehension of the metabolic and molecular basis of other facets of ageing muscles, beyond those occurring in protein metabolism (e.g. ectopic lipids, satellite cells dysfunction), are needed to generate a more holistic appreciation of the effects of ageing on skeletal muscle in relation to deleterious functional and metabolic outcomes.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA423

Muscle insulin resistance, immobilisation and remobilisation

F. Dela

Xlab - Center for Healthy Aging, University of Copenhagen, Copenhagen, Denmark

A family history of type 2 diabetes (e.g. first degree relatives, FDR) and low birth weight (LBW) are risk factors of type 2 diabetes and predisposes to type 2 diabetes via genetically and environmental susceptibility, respectively. Severe physical inactivity could purposely unmask their predisposal and reveal a larger vulnerability to physical inactivity than those without preexisting risk factors. Furthermore, comparisons between FDR and LBW in the response to alterations in the daily physical activity level may exemplify the relative influence of genes and environmental factors. We have studied such groups before and after a ten-day bed rest intervention study, which was followed by a four wk re-training program. Thirteen FDR (age: 26 ± 1 yr; body weight 80 ± 3 kg; BMI: 25 ± 1; VO2max: 39 ± 1 ml/min/kg), twenty LBW (age: 26 ± 1 yr; body weight 72 ± 3 kg; BMI: 23 ± 1; VO2max: 44 ± 3 ml/min/kg) and twenty healthy controls (CON) (age: 25 ± 1 yr; body weight 78 ± 2 kg; BMI: 24 ± 1; VO2max: 44 ± 1 ml/min/kg) was included in the study (Sonne et al., 2010). Insulin secretion and action, endothelial function, inflammation, and muscle transcriptional and translational changes was studied in a comprehensive experimental program.
Aging per se does not lead to skeletal muscle insulin resistance (Dela et al., 1996b;Dela et al., 1996a), but with age physical inactivity may develop. Data from a study on how one-legged immobilization for 2 wks with subsequent 6 wks rehabilitation may change markers on insulin sensitivity in young and old men will be reported.

Ageing, inactivity and rehabilitation

C. Suetta

Glostrup Hospital, Copenhagen, Denmark and University of Copenhagen, Copenhagen, Denmark

Skeletal muscle atrophy is a common debilitating condition associated with human immobilisation and ageing resulting in a reduced muscle function. In animal models, loss of muscle mass with immobilisation or unloading has been suggested primarily to occur through an accelerated degradation of myofibrillar proteins via the ubiquitin-proteasome pathway, although rapid decreases in protein synthesis also has been shown. Somewhat in contrast, studies in young human individuals have suggested that a decline in protein synthesis rather than accelerated protein breakdown is responsible for the muscle loss observed with disuse. With aging, muscle loss is suggested to be associated with increased inflammation, decreased anabolic signalling, increased apoptosis, impaired myogenic responsiveness as well as decreased mitochondrial function. Moreover, aging has been found to affect signalling pathways that regulate myogenic growth factors and myofibrillar protein turnover in skeletal muscle of rodents. However, very little is known about how immobilisation and skeletal muscle disuse affects ageing muscle. We therefore set to investigate some of the cellular and molecular mechanisms suggested being responsible for the age-related changes in skeletal muscle with disuse and re-growth, including the differential involvement and time course of such signalling pathways.
Recent data from our group indicate that, although immobility induces muscle atrophy in both young and old individuals, the loss in muscle mass is more pronounced in young. Yet, the elderly, compared to young individuals, required a prolonged recovery phase in order to return to initial muscle mass levels following short-term immobilisation. An age-specific regulation of the signalling pathways orchestrating the initiation and time-course of human disuse muscle atrophy was therefore hypothesized and a range of genes from signalling pathways previously demonstrated to play a central role in the regulation of skeletal muscle atrophy and hypertrophy in a variety of animal models was profiled. Collectively, our findings indicate that the time-course and regulation of human skeletal muscle atrophy is age-dependent, leading to an attenuated loss in aging skeletal muscle when exposed to longer periods of immobility-induced disuse. Moreover, age-specific differences may exist for the ability of human skeletal muscle to regenerate after immobility-induced muscle atrophy.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

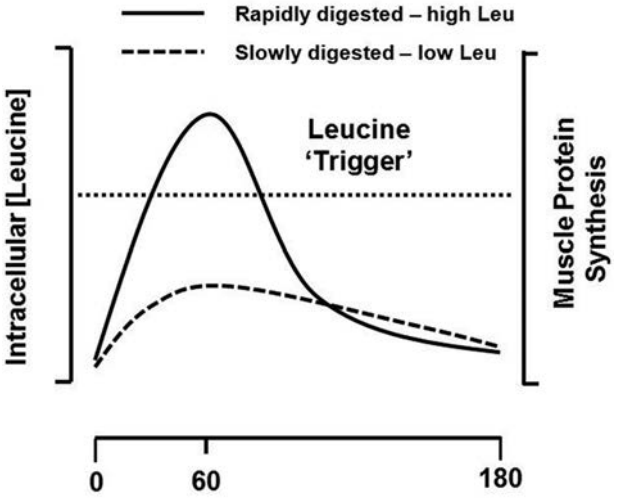
SA425

Maximising muscle protein synthesis: influence of nutrition and resistance training modalities

S.M. Phillips

Kinesiology, McMaster University, Hamilton, ON, Canada

Muscle proteins are constantly and simultaneously being synthesized and degraded. This 'turnover' provides for a mechanism of constant maintenance and greater potential for changes in protein pool size. The two most potent stimuli for enhancing muscle protein synthesis (MPS) are exercise and provision of protein. While protein feeding and exercise are independent stimulators of MPS they are additive in their effect and when combined over longer periods of time sum to result in expansion of a protein pool, the most obvious example of which is muscle fibre hypertrophy with resistive exercise (Phillips et al., 2005). The traditional dichotomy for the phenotypic adaptation induced by exercise is that endurance exercise does not lead to hypertrophy but instead results in expansion of the mitochondrial protein pool. On the other hand resistance exercise leads to muscle fibre hypertrophy (i.e., expansion of the myofibrillar protein pool) and does not change mitochondrial content. Our work has shown that in the untrained state the response to exercise is, however, rather generic and that both protein pools expand, at least acutely (Wilkinson et al., 2008). With increased specificity and time spent training with one particular exercise mode the response is 'honed' and the protein pools that are synthesized become specific (Wilkinson et al., 2008). With a focus on resistive exercise, since it is a potent countermeasure to atrophy even in small doses and an effective countermeasure to sarcopenic muscle loss, we have shown that various paradigms of resistance exercise that are non-traditional are actually effective in stimulating MPS (Burd et al., 2010;Burd et al., 2012a) and also in promoting hypertrophy (Mitchell et al., 2012). In combination with our work on optimal sources of protein to promote MPS (Tang et al., 2009;Burd et al., 2012b) we are now beginning to formulate strategies for older persons and persons with limited mobility to restore muscle mass as effectively as possible. In short, rapidly digested high-leucine content proteins such as whey protein are remarkably effective in stimulating MPS (Tang et al., 2009;Burd et al., 2012b); The figure below is a schematic representation of the 'leucine trigger' hypothesis showing how the rise in intramuscular free leucine, likely through mTOR signalling, stimulates MPS. Noteworthy is the fact that slowly digested or lo leucine-containing proteins are ineffective in stimulating MPS. We have begun to use the information we have gathered in young men in older persons with compromised muscle mass who embody a condition known as 'anabolic resistance'. Anabolic resistance in aging describes a condition in which older persons have an impaired ability to mount a robust anabolic response to usually anabolic stimuli like protein/amino acid feeding and resistance exercise. The reasons for anabolic resistance are not completely clear but likely involve defects in protein signalling, reductions in microvascular perfusion, and potentially a number of molecular-level maladaptative age-related changes. Data from our lab shows that older persons become anabolically resistant with even small periods of relative inactivity and that such periods are more common in aging and likely contribute to the sarcopenic muscle loss. something that is prevalent with aging and with muscle disuse. Strategies to effectively combine exercise and protein ingestion will be discussed and new data presented on how this applies to aging and disuse.



A schematic illustration of the 'leucine trigger' thesis: the rise in intracellular leucine is an initiating and crucial event in the stimulation of muscle protein synthesis (MPS). Rapidly digested and high leucine-content proteins are effective stimulators of MPS, whereas slowly digested proteins or those that contain low leucine are not as effective.

Beta-adrenergic signalling in Takotsubo cardiomyopathy

S.E. Harding, H. Paur, P. Wright, M. Tranter, M. Sikkel, J. Gorelik and A. Lyon

NHLI, Imperial College, London, UK

There has been a rapid growth of individual case reports and larger series describing a new syndrome of acute and severe,

but reversible, heart failure – Takotsubo cardiomyopathy (TC). This syndrome usually follows an identifiable emotional, psychological or physical stress and mimics symptoms of acute myocardial infarction. It is characterised by regional wall motion abnormalities, classically an apical ballooning due to a hypercontractile base of the heart but poorly contracting or "stunned" apex. However, its most surprising characteristic is the rapid (days to weeks) recovery of many patients, usually from severe impairment to full health with subsequent good prognosis. For such a profound depression of contraction, deaths are relatively infrequent (1-3%) and, in that small percentage of patients in which the syndrome recurs, recovery is again complete. It is this ability to recover which makes the syndrome of such interest, since equivalent changes in chronic heart failure would be considered end-stage. This begins to lead us to the hypothesis that the cardiodepression is linked to some physiological strategy of benefit to the organism.
Evidence points to adrenaline as the precipitating factor. Catecholamine levels in TC patients 1-2 days after presentation are higher than those MI: adrenaline falls back to MI levels only after 7-9 days. Particularly, the reproduction of the signs of TC by accidental administration of adrenaline (including single intramuscular 1mg doses from an 'Epi-pen') is most indicative of its central role. Adrenaline activates beta2AR as well as beta1ARs and the beta2AR is pleiotropic, having the potential to couple through Gs-AC-cAMP (like the beta1AR) but also though Giapha, Gbetagamma and non-G-protein pathways. The ability of different agonists to drive the beta2AR towards one or other coupling partners is known as biased agonism or stimulus trafficking. We had found in other circumstances that adrenaline at high concentrations could show biased agonism towards Gi coupling, with switch from a positive to negative inotropic response, and hypothesised that this was underlying the depression of contraction.
In order to investigate this hypothesis and the underlying pathophysiological mechanisms, we have developed a model of TC in which an anaesthetised rat receives an intravenous (jugular) bolus of adrenaline (equivalent to ~5mg in an adult human) (Paur et al Circulation 2012). Intravenous bolus delivery was selected to mimic the human physiological response to sudden high stress. Adrenaline bolus triggered a marked decrease in cardiac contraction initiating at 15 min and reversing within an hour: this was localised to apex and mid-LV, a hallmark of TC. We showed that isolated apical cardiomyocytes demonstrated an increased beta2:beta1 ratio and greater beta2AR-specific contractile responses compared to paired basal cardiomyocytes isolated from the same heart. Importantly noradrenaline, which has a lower affinity at the beta2AR and is far weaker at producing beta2AR -Gi signalling, did not reproduce the effect of adrenaline. The negative effect of adrenaline was completely abolished by pertussis toxin, providing strong evidence for a Gi-dependent mechanism of action. Importantly, beta-blockers which demonstrate biased agonism of the beta2AR to Gi have an additive negative inotropic effect when added at the peak of the adrenaline-induced cardiodepression. The downstream mediator of negative inotropism appeared to be through p38 MAP kinase. We found evidence that the Gi/p38 negative inotropic signalling was cardioprotective as well as cardiodepressant, since blocking beta2AR or p38 MAPK precipitated a significantly increased incidence of sudden death in the adrenaline-treated animals.
In summary, we have evidence that Takotsubo Cardiomyopathy is a result of beta2AR biased agonism to Gi pathways at high adrenaline levels. We hypothesise that this is part of a protective strategy to prevent catecholamine damage but that transient cardiodepression can be a consequence in particular individuals.

Spatio-temporal dynamics of cAMP-dependent protein kinase in cardiac myocytes

G. Vandecasteele

Inserm UMR-S 769 / Labex LERMIT, University Paris Sud, Châtenay-Malabry, France

β-adrenergic receptors enhance cardiac contractility by increasing cAMP levels and activating the cAMP-dependent protein kinase (PKA). PKA phosphorylates several key excitation-contraction coupling proteins, including L-type Ca^{2+} channels at the plasma membrane. However, PKA regulates numerous other effectors in cardiac myocytes, and notably nuclear effectors ultimately leading to hypertrophic remodelling and heart failure. In the last few years, our group has contributed to the recognition that physiological cAMP signaling is confined in specific subcellular domains and identified cyclic nucleotide phosphodiesterases (PDEs) as crucial regulators of compartmentalized cAMP signals and local PKA activity. This presentation will briefly summarize published data regarding the regulation of L-type Ca^{2+} current by type 4 phosphodiesterases (PDE4) and the implication for cardiac arrhythmias. It will then focus on the regulation of cytoplasmic *versus* nuclear PKA activity in cardiac myocytes, visualized by FRET-based A-kinase activity reporters targeted to these compartments. The role of PDEs as well as Ser/Thr phosphatases in the differential integration of the PKA response to β-adrenergic stimulation will be discussed.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA428

Targeting β-AR signalling in heart disease through G-protein receptor kinases

P. Most

Department of Internal Medicine III, University of Heidelberg, Heidelberg, Germany

Abnormal β-adrenergic receptor (β-AR) signalling is considered a hallmark of congestive heart failure driving its progression towards contractile failure and lethal tachyarrhythmias. Although advanced understanding of underlying molecular abnormalities has been gleaned from experimental research, β-AR blockade remains to date the only therapeutic intervention that shields the heart from noxious sympathetic overdrive. The aim of this paper is to discuss therapeutic innovations targeting dysfunctional G-protein-coupled receptor kinase (GRK) activity beyond β-AR blockade and highlight translational strategies that embark on proof-of-concept studies in small and large animal HF models for therapeutic modulation of the GRK2- and Gbγ-protein dependent signalling.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA429

Compartmentalized beta-adrenergic receptor signalling to cAMP in healthy and failing cardiomyocytes

V. Nikolaev

Heart Research Center Göttingen, Götttingen, Germany

The ubiquitous second messenger cAMP is an important regulator of cardiac function and disease. In cardiomyocytes, cAMP signalling is organized in discrete subcellular microdomains which are often involved in calcium cycling and lead to temporal and spatial segregation of subcellular cAMP responses. To directly visualize cAMP dynamics in such microdomains, we generated two novel targeted fluorescence resonance energy transfer (FRET)-based biosensors and expressed them in cardiomyocytes of transgenic mice under the alpha-myosin heavy chain promoter. The first sensor reports local cAMP dynamics associated with the sarcolemmal T-tubular microdomains and the second one can visualize cAMP directly at the sarcoplasmic reticulum calcium ATPase 2 (SERCA2)
Echocardiography, immunostaining and cell fractionation analysis confirmed the absence of any adverse cardiac phenotype and the proper localization of the sensors in transgenic mouse hearts. Local cAMP signals were measured in single freshly isolated adult ventricular myocytes and compared to cAMP dynamics in the bulk cytosolic compartment. FRET measurements revealed the predominant role of phosphodiesterase type 4 (PDE4) in the regulation of basal cAMP levels in the SERCA2 compartment and PDE3 in the regulation of the beta2-adrenergic receptor stimulated cAMP pools at the T-tubules. In failing cardiomyocytes, isolated from mouse hearts 8 weeks after transverse aortic constriction, these local PDE4 and PDE3 activities were severely reduced which led to specific subcellular changes in cAMP compartmentation
In conclusion, through generation of novel FRET biosensors and transgenic models, we were able to get direct insights into localized cAMP signaling in various subcellular microdomains and to unravel its changes in a cardiac disease model.

SA430

Cyclic nucleotides, physiology and function in heart disease

M. Zaccolo

University of Oxford, Oxford, UK

Catecholamine-dependent cAMP signalling is a key regulator of excitation-contraction coupling and the incorrect activation of this pathway is a hallmark of disease states such as cardiac hypertrophy and heart failure (HF). In addition to β-adrenergic receptors (β-AR), several other types of Gs-coupled receptors signal in the heart through the generation of cAMP. Cardiac signalling of different cAMP-elevating hormones has long been known to result in distinct functional outputs. This observation has led to the recognition that mechanisms must be in place that allow for specificity of response and that alterations of such mechanisms may result in cardiac disease, although the nature of such mechanisms and the disease-associated changes are poorly defined. The question of how cAMP signalling fidelity is achieved is therefore of fundamental importance for understanding cardiac function in health and disease. Spatial control of cAMP signal propagation has emerged as a key mechanism responsible for specificity of response. That is, activation of individual GPCRs generates spatially restricted pools of cAMP within distinct subcellular compartments, leading to the activation of selected subsets of the cAMP effector, protein kinase A (PKA). PKA subsets are clustered on a scaffold of A-kinase anchoring proteins (AKAPs) into microdomains together with other key downstream elements of the signalling cascade and in the vicinity of specific effectors such as receptors, phospholamban, and ion channels. Based on this model, contractility is affected by changes in cAMP levels in a defined subcellular compartment whereas cAMP changes in other compartments may affect gene transcription or apoptosis, for example.
Although HF is characterized by down regulation of cAMP signals, elevation of cAMP via activation of the adrenergic system in HF patients correlates directly with shortened survival. This apparent paradox may be explained by failure to achieve the necessary spatial accuracy when manipulating bulk cAMP levels through β-AR activation, resulting in deleterious, off-target effects. Therefore a detailed understanding of the molecular mechanisms that regulate compartmentalised cAMP signalling may help developing novel strategies for the treatment of heart disease.
We are using a combination of real-time imaging, biochemical and genetic approaches to study the spatio-temporal dynamics of cAMP in intact living cells. We aim at understanding the architectural and regulatory principles by which intracellular cAMP signalling networks achieve the plasticity and context-sensitivity necessary for a cardiac myocyte to function and we are dissecting how alterations of these networks may be responsible for the development of cardiac disease.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA431

Interaction of endothelial connexins: Can they mutually replace each other at the functional level?

C. de Wit

Institut für Physiologie, Universität Lübeck, Lübeck, Germany and DZHK (German Centre for Cardiovascular Research), partner site Hamburg/Kiel/Lübeck, Lübeck, Germany

Connexin40 (Cx40) is a crucial component in gap junctions (GJ) with a strong impact on cardiovascular and renal physiology since Cx40-deficient mice exhibit pronounced hypertension, altered negative feedback of renin secretion causing an increased plasma renin activity, and impaired conduction of endothelium-dependent dilations. Cx40 is expressed abundantly in endothelial and renin-producing cells and we assessed the effects of cell-specific Cx40 deletion. Expectedly, lack of Cx40 in renin-producing cells led to hypertension that was renin-dependent since low-salt diet and blockade of angiotensin-converting enzyme abrogated the enhanced arterial pressure. In contrast, deletion of Cx40 in endothelial cells did not elevate arterial pressure but strongly reduced the conduction of endothelium-dependent dilations in the microcirculation similar to global Cx40-deficient mice. Such attenuation was not present in hypertensive mice being deficient for

Cx40 in renin-producing cells. Thus, a vascular and a renal phenotype can be well distinguished. Notably, the expression of the second connexin that is found abundantly in endothelial cells (Cx37) is strongly reduced in conducting arteries and lacking in arterioles in global Cx40-deficient hypertensive mice. This altered expression of Cx37 is not related to the hypertension, but solely due to the lack of Cx40 because it was also observed in normotensive endothelial-cell specific but not in hypertensive renin-producing cell specific Cx40-deficient mice. These findings raise the question if the defect in the conduction of dilatory signals along arterioles is indeed related to the lack of Cx40 or if the combined deletion of Cx40 and Cx37 is required to produce this effect. Hitherto, we studied animals carrying a mutated non-conducting Cx40 identified in humans (Ala96->Ser, A96S). In these animals, the conduction of endothelium-dependent dilation is similarly impaired despite the fact that the non-conducting mutated Cx40 as well as Cx37 was identified in endothelial cell membranes in arterioles by immunohistochemistry. This suggests that Cx37 cannot support the conduction of dilatory signals in arterioles in the absence of a functional Cx40. Moreover, animals carrying this mutated Cx40 were also hypertensive suggesting similar mechanisms with regard to Cx40 function in renin-producing cells. Thus, we conclude that Cx40 is the most important connexin in cardiovascular and kidney physiology.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Role of Pannexin 1 in the regulation of blood pressure

M. Billaud[1,2], T. Parpaite[1], Y. Chiu[3], A.W. Lohman[1,2], S.M. Mutchler[2], J.K. Sandilos[3], D.A. Bayliss[3] and B.E. Isakson[1,2]

[1]Department of Molecular Phyiology and biological Physics, University of Virginia, Charlottesville, VA, USA, [2]Robert M Berne Cardiovascular Research Center, University of Virginia, Charlottesville, VA, USA and [3]Department of Pharmacology, University of Virginia, Charlottesville, VA, USA

We demonstrated that pannexin1 (Panx1) channels are expressed in the smooth muscle cells of small arteries where they participate in α1D adrenergic receptor (α1DAR)-mediated vasoconstriction[1]. In this paper, we also showed that ATP is released from vascular smooth muscle cells via Panx1 channels upon phenylephrine (PE) stimulation. Since the α1DAR-mediated constriction as well as ATP signaling are key in the regulation of peripheral resistance and blood pressure, we hypothesized that Panx1 could participate in blood pressure regulation. Therefore, we created an inducible conditional KO mouse model where Panx1 is deleted specifically in smooth muscle cells by breeding smooth muscle myosin heavy chain (SMMHC) - $CreER^{T2+}$ mice with $Panx1^{fl/fl}$ mice. After 10 days of tamoxifen injections, the expression of Panx1 in arterial smooth muscle cells was abolished and the vasoconstriction of small arteries in response to PE was significantly reduced. Using radiotelemetry, we measured a reduction in the mean arterial pressure in these mice after tamoxifen injections. Because Panx1 is activated by the α1DAR signaling cascade and because the channel and the receptor are closely located at the plasma membrane of arterial smooth muscle cells, we hypothesized that disruption of the Panx1/α1DAR signaling pathway would alter vasoconstriction. In order to specifically inhibit Panx1 activation by the α1DAR, we designed a peptide mimicking the intracellular loop (IL) region of Panx1, which is enriched in proline, making this region more susceptible to interact with protein partners for intracellular signaling. When treated with the IL peptide, pressurized small arteries exhibited decreased vasoconstriction to PE. In parallel, we performed electrophysiology on HEK cells co-transfected with Panx1 and α1DAR plasmids and confirmed PE-induced Panx1 activation in vitro by measuring an increase of Panx1 current and ATP release upon PE stimulation. The PE-induced Panx1 activation was also altered by Panx1 IL peptide. To further investigate the key amino acids of Panx1 intracellular loop in PE-induced Panx1 activation, we created specific mutants of Panx1 in the region mimicked by the IL peptide and cotransfected these mutants in HEK cells along with the α1DAR plasmid. Both ATP release and Panx1 currents were decreased when the amino acids YLK in position 198 to 200 were mutated to alanine, showing their essential role in PE-induced Panx1 activation. In summary, our results show that Panx1 plays an essential role in the α1DAR-mediated constriction by releasing ATP and thus in the regulation of blood pressure. Furthermore, we have identified a key region in Panx1 intracellular loop that is essential in the PE-induced activation of Panx1. This work provides the basis for a novel understanding of blood pressure control by the sympathetic nervous system.

SA433

Cellular mechanisms mediated by connexin channels involved in the control of blood pressure

J. Haefliger

medicine, CHUV, Lausanne, Vaud, Switzerland

Connexins (Cxs) form connexons within the plasma membrane to create domains referred as gap junctions. The intercellular channels established by the pairing of two connexons allow for the diffusion of ions and molecules between adjacent cells. Vascular Cxs play a role in the contractility of the vessel wall by allowing the exchange of signaling molecules to coordinate the activity of the smooth muscle cells (SMCs) and the endothelial cells (ECs). In the vascular wall, four Cxs are mostly expressed: Connexin37 (Cx37) and Cx40 in ECs and Cx43 and Cx45 in SMCs. To investigate the effects of chronic hypertension on vascular Cxs in the aorta, Wild-type (WT) mice and mice lacking Cx40 (Cx40-/-), a genetic model of renin-dependent hypertension were subjected to either a two-kidney, one-clip (2K1C) procedure associated with elevated angiontensinII levels (AngII) or to N-nitro-l-arginine-methyl-ester (L-NAME) treatment, which induce renin-dependent and -independent hypertension, respectively. All hypertensive mice featured a thickened aortic wall, increased levels of Cx37 and Cx45 in SMCs, and of Cx40 in ECs (except in Cx40-/- mice). Cx43 was up-regulated only in the SMCs of renin-dependent models of hypertension. Blockade of the renin-angiotensin system of Cx40-/- mice normalized blood pressure and prevented both aortic thickening and Cx alterations. Ex vivo exposure of WT aortas, carotids, and mesenteric arteries to physiologically relevant levels of AngII increased the levels of Cx43, but not of other Cxs. In the aortic SMCs line A7r5, AngII activated kinase-dependent pathways and induced binding of the nuclear factor-kappa B (NF-kappaB) to the Cx43 gene promoter, increasing Cx43 expression. These data suggest that Cx43 is selectively

increased in renin-dependent hypertension via an AngII activation of the extracellular signal-regulated kinase and NF-kappaB pathways.
Upon agonist stimulation, ECs trigger smooth muscle relaxation through the release of relaxing factors such as nitric oxide (NO). We investigated the link between the expression of endothelial Cxs (Cx40 and Cx37) and endothelial nitric oxide synthase (eNOS) expression and function in the mouse aorta. We demonstrated that acetylcholine (ACh)- and ATP-induced endothelium-dependent relaxations solely depend on NO release in both WT and Cx40-/- mice, but are markedly weaker in Cx40-/- mice. Consistently, both basal and ACh- or ATP-induced NO production were decreased in the aorta of Cx40-/- mice. Altered relaxations and NO release from aorta of Cx40-/- mice were associated with lower expression levels of eNOS in the aortic endothelium of Cx40-/- mice. We further demonstrate that eNOS, Cx40, and Cx37 tightly interact with each other at intercellular junctions in the aortic endothelium of WT mice, suggesting that the absence of Cx40 in association with a marked decrease of Cx37 levels in ECs from Cx40-/- mice participate to the decreased levels of eNOS. To investigate changes in vascular Cxs and eNOS during hypertension in mice aorta, WT mice and Cx40-/- were subjected to either one-kidney, one-clip (1K1C; volume overload model) or 2K1C surgery procedure. Mean blood pressure was 10% higher in the 1K1C Cx40-/- mice compared to the other hypertensive models (Cx40-/-, 2K1C Cx40-/-, 2K1C WT and 1K1C WT), due to the association of a renin-dependent and -independent hypertension. eNOS phosphorylation was specifically increased in the aortic endothelium of 1K1C Cx40-/- mice showing that the increased mechanical forces impinging on the aortic wall were elicited by the association of renin-dependent and independent hypertension, further suggesting a compensatory mechanism associated with decreased eNOS levels in the Cx40-/- mice. Finally, to investigate the role of Cx40 in the propagation of Ca2+ waves in the endothelial cells of the mouse aorta, we performed Ca2+ imaging on intact aortic endothelium from both WT and Cx40-/- mice. ACh induced Ca2+ signaling in a fraction of ECs expressing the M3 muscarinic receptors. Inhibition of intercellular communication using carbenoxolone or octanol fully blocked the propagation of ACh-induced Ca2+ transients toward adjacent cells in WT and Cx40-/- mice. As compared to WT, Cx40-/- mice displayed a reduced propagation of ACh-induced Ca2+ waves, indicating that Cx40 contributes to the spreading of Ca2+ signals. These findings provide evidence that 1) different types of hypertension are associated with a differential regulation of Cxs expression in SMC and ECs layers; 2) ECs Cxs play a role in the regulation of eNOS expression and function in response to hypertension; 3) Cx40 and Cx37 contribute to the propagation and amplification of the Ca2+ signaling triggered by ACh in ECs expressing the M3 muscarinic receptors.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA434

Connexins in ischemia-reperfusion injury

S. Morel[1], V. Braunersreuther[2], E. Sutter[1], G. Pelli[1], B. Foglia[1], F. Mach[2] and B. Kwak[1,2]

[1]Department of Pathology and Immunology, University of Geneva, Geneva, Switzerland and [2]Department of Internal Medicine – Division of Cardiology, University of Geneva, Geneva, Switzerland

Intercellular channels formed by connexins (Cx) have been shown to play a critical role in cardiovascular disease. For instance, vascular Cx43 influences atherosclerosis development and plaque stability, and cardiac Cx43 may determine the development of arrhythmias after myocardial infarction. In the heart, Cx40 is expressed in atrial cardiomyocytes, the conduction system and in endothelial cells, whereas Cx37 is only found in the endothelium. Here, we investigated the implication of the two endothelial connexins during ischemia and reperfusion in mice.
For this purpose, we used the Cre-loxP system to create a mouse line in which Cx40 is deleted from the endothelium only. Immunostainings on TIE2-Cre+Cx40fl/flApoE-/- mice confirmed the absence of Cx40 in the endothelium, whereas the protein was normally expressed in the atria and cardiac conduction system. Moreover, Cx40 was normally expressed in the endothelium, atria and conduction system of TIE2-Cre+Cx40wt/wtApoE-/- and TIE2-Cre-Cx40fl/flApoE-/- control mice. Sixteen-week-old mice were subjected to in vivo left coronary artery occlusion for 30 minutes and sacrificed 24-hours after reperfusion for analysis of infarct size and infiltration of inflammatory cells. Myocardial surface areas at risk and infarcted areas were measured from computed images using NIH Image software. Areas at risk, normalized to total left ventricle surface areas, were similar between the experimental groups, i.e TIE2-Cre+Cx40wt/wtApoE-/-: 29.2±1.2% (N=11), TIE2-Cre-Cx40fl/flApoE-/-: 33.7±3.7% (N=9), and TIE2-Cre+Cx40fl/flApoE-/- 31.7±2.2% (N=11, n.s.). Interestingly, the infarct area, normalized to areas at risk, was significantly increased in TIE2-Cre+Cx40fl/flApoE-/- (20.2±3.1%, P<0.05) mice as compared to controls (10.1±2.0% and 11.3±1.8%). Moreover, we performed immunofluorescent stainings against Ly6G to detect neutrophils in the infarcted heart. We showed that neutrophil infiltration was significantly higher in TIE2-Cre+Cx40wt/wtApoE-/- mice (24.2±3.1%, P<0.01, N=4) in comparison with controls (9.8±1.8%, N=5 and 8.5±1.7%, N=5). In a previous study, we demonstrated that endothelial-specific deletion of Cx40 promotes atherosclerosis by increasing CD73-dependent leukocyte adhesion to the endothelium. To determine whether this interaction also plays a role in ischemia-reperfusion injury, CD73-/-ApoE-/- mice have been submitted to in vivo ischemia-reperfusion. Whereas the area at risk in this group of mice was similar to those measured in the previous groups (31.3±3.6%, N=8), the infarcted area was significantly increased in comparison with control mice (18.2±1.6%, P<0.01). Treatment of TIE2-Cre+Cx40wt/wtApoE-/- mice with methotrexate, a CD73 activator, significantly reduced the infarcted area (8.5±1.3%, P<0.05, N=10) as compared to TIE2-Cre+Cx40wt/wtApoE-/- mice without treatment. Finally, hearts from TIE2-Cre+Cx40wt/wtApoE-/- mice and control mice have been submitted to ex vivo ischemia-reperfusion by using a Langendorff perfusion system. Areas at risk and infarct size were similar between the three groups. To investigate the possible implications of another endothelial connexin in myocardial infarction, Cx37-/-ApoE-/- mice were submitted to the same protocol of in vivo ischemia-reperfusion. Areas at risks were

similar between Cx37-/-ApoE-/- and control ApoE-/- mice, and the infarcted area appeared also not affected by the deletion of Cx37 (Cx37-/-ApoE-/-: 13.8±1.3%, ApoE-/-: 14.7±2.7%, N=12, n.s.).
We conclude that endothelial Cx40, but not Cx37, is implicated in resistance of the heart to ischemia-reperfusion injuries, such as cell death and inflammatory infiltration, by a CD73-dependent pathway. These findings may point towards a specific novel therapeutic target to limit the cardiac injury after coronary interventions.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA435

Gap junctions in the pulmonary artery: from physiology to pulmonary hypertension

C. Guibert

Centre de Recherche Cardio-Thoracique de Bordeaux, INSERM U1045, Bordeaux, France and Centre de Recherche Cardio-Thoracique de Bordeaux, Université Bordeaux Segalen, Bordeaux, France

Intercellular channels or gap junctions (GJ) are formed by connexin (Cx) proteins, transmembrane proteins that play a pivotal role in the direct movement of ions and larger cytoplasmic solutes between vascular endothelial cells (EC), between vascular smooth muscle cells (SMC), and between endothelial and smooth muscle cells (myoendothelial junctions). GJ are clusters of intercellular channels resulting from the connection of two hexameric assembly of Cx (hemichannels). Hemichannels are localized on the membrane of two adjacent cells and arranged with identical or different Cx (21 isoforms in human) with various possible combinations. Such process has functional consequences and provides an efficient cellular strategy to finely regulate cell-to-cell communication in the vascular wall. The expression of different GJ proteins is dynamically regulated throughout different types of vascular bed in healthy vessels and in vascular disease states such as atherosclerosis, systemic and pulmonary hypertension (PH) and diabetes. Our studies focus on the role of intercellular communications (Cx) in the physiology and pathophysiology of the pulmonary arterial vascular bed.
In the pulmonary circulation, endothelial control of smooth muscle tone is of critical importance to maintain low pressure and low resistance. In this connection, most of the medical treatments used in PH (e.g., NO, prostacyclin…) mimic and amplify the physiological control of EC on SMC. Myoendothelial junctions may thus potentially participate in this process. We demonstrated that Cx 37, 40 and 43 are expressed and functional in small intrapulmonary arteries (IPA) from rat. Interestingly, resistance vessels are very important for blood flow regulation and the incidence of myoendothelial gap junctions is higher in resistance than in conduit arteries. We also showed that 5-HT, a potent vasoconstrictor whose concentration is increased in PH, produces superoxide anion ($O_2^{\bullet-}$) in the smooth muscle and NO in the endothelium. $O_2^{\bullet-}$ passes through the myoendothelial junctions to decrease endothelial NO production and thus strengthen pulmonary vasoreactivity (Billaud M *et al.*, 2009). Unlike 5-HT, endothelin-1 (ET-1) and phenylephrine (Phe, an α1 adrenoceptor agonist) do not produce $O_2^{\bullet-}$ in IPA. We investigated the signalling pathways involved in 5-HT-induced $O_2^{\bullet-}$ production in rat IPA by focusing on the sources of reactive oxygen species (ROS), the role of intra and extracellular calcium and the role of caveolae. This 5-HT-induced production of $O_2^{\bullet-}$ is mediated by 5-HT2A receptors, is dependent on the complex I of the mitochondrial respiratory chain and NADPH oxidases and extracellular calcium influx plays an important role in this process (Khoyrattee N *et al.*, 2012). We also demonstrated that the main candidates involved in this signaling pathway are localized within/close to caveolae. This is the first time that a negative control of the endothelial NO function by the smooth muscle is demonstrated.
PH is a multifactorial disease characterized by a progressive increase in pulmonary vascular resistance caused by vasoconstriction, vascular cell proliferation and obliteration of pulmonary microvasculature. These processes lead to right heart failure and ultimately to death. PH occurs in a variety of clinical situations and is associated with a broad spectrum of histological patterns and molecular abnormalities. Because of this diversity, early diagnosis is difficult and efficient treatments are still lacking. The recent revision of the classification of PH distinguishes five groups. Among these groups, the category 1 PH also known as pulmonary arterial hypertension (PAH) includes idiopathic PAH, familial PAH and acquired PAH, the latter of which being associated with other diseases such as HIV or connective tissue diseases. The non-category 1 PH previously known as secondary PH includes the category 3 which is a widely distributed PH secondary to alveolar hypoxia as a result of lung disease such as chronic obstructive pulmonary disorder (COPD). Although, PH has progressively evolved from a fatal to a chronic disease, none of the currently available therapies is curative. Despite intensive research, PH remains an important medical challenge and a better knowledge of the underlying molecular and cellular mechanisms remains crucial for the development of new or additional innovative therapies. By using different rat models of PH (category 1 and 3) and heterozygous knock-out mice for Cx43, we highlighted Cx43 was overexpressed in PH rats and Cx have some role in the contractile response to stimuli, already known to be involved in PH, namely 5-HT, ET-1, Phe and depolarising solutions (high potassium solutions) (Billaud M *et al.*, 2011; Khoyrattee N *et al.*, 2012).
Future directions will be thus to consider Cx as new therapeutic targets and strategies in pulmonary hypertension.

A new take on uptake: neurotransmitter transporters and the cellular mechanisms of amphetamine action

S.G. Amara

National Institute of Mental Health, National Institutes of Health, Bethesda, MD, USA

Neurotransmitter transporters present at the plasma membrane contribute to the clearance and recycling of neurotransmitters and have a profound impact on the extent of receptor activation during neuronal signaling. These carriers also are the primary targets for psychostimulant drugs of abuse, antidepressant medications, and drugs such as

methylphenidate and amphetamines, which are used to treat attention deficit disorders in children. In recent studies we have observed that once amphetamine-like drugs enter dopamine neurons they activate multiple intracellular signaling pathways to trigger changes in the cellular trafficking of the dopamine transporter and other neuronal membrane proteins. Within the cell amphetamines activate the small GTPases, Rho and Rac1 and trigger endocytosis of the dopamine transporter (DAT) by a RhoA- and dynamin-dependent pathway. We have also found that increases in cAMP and PKA activity mediated by D1/D5 dopamine receptors or by amphetamine itself, serve as a break on DAT internalization, revealing interplay between PKA and RhoA signaling in the regulation of DAT activity. This work implies that amphetamine-like drugs not only block monoamine transport and potentiate neurotransmitter action, but also act on specific cytoplasmic targets that regulate protein trafficking and many other cellular activities. Although several key steps in the process remain to be defined, this novel intracellular mode of amphetamine action has major implications for the mechanisms of neuroplasticity and neurotoxicity associated with psychostimulant use and suggests novel drug targets for modulating the actions of amphetamines.

Dendritic inhibition by DAT-mediated dopamine-release

B. Falkenburger

Neurology, RWTH University, Aachen, Germany

Neurotransmitter transporters take up neurotransmitter secreted by exocytosis. I will discuss our published work indicating that the dopamine transporter may, in addition, secrete dopamine from dendrites of dopaminergic neurons when glutamatergic inputs are activated. Similar phenomena may occur for further transmitters. Since this finding has remained controversial, I will include descriptions of transporter-mediated neurotransmitter release by other groups.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Molecular physiology and pathophysiology of glutamate transporter-associated anion channels

C. Fahlke

Institue of Complex Systems, Zelluläre Biophysik (ICS-4), FZ Jülich, Jülich, Germany

Excitatory amino acid transporters (EAATs) do not only mediate secondary-active glutamate transport, but also anion-selective currents. EAAT anion currents are small in the absence and increase upon application of L-glutamate due to substrate-dependent gating of EAAT anion channels. At present, neither the molecular basis nor the physiological importance of the EAAT anion conductance is sufficiently understood. Anion channel gating can be described by a kinetic scheme that is based on the glutamate transport cycle and in which anion channel opening is associated with certain states. All voltage- and substrate-dependent conformational changes of EAAT anion channels are linked to transitions within the transport cycle, and there are no indications for additional substrate—dependent anion channel opening and closing transitions. To account for the substrate dependence of macroscopic currents different transporter states might either exhibit distinct unitary conductances or distinct anion channel open probabilities. Macroscopic current recordings and noise analysis revealed a single channel conductance of 1 pS at symmetrical NO3- for EAAT4 anion channels in the absence as well as in the presence of glutamate (Kovermann et al., 2010). All our experimental data are consistent with opening of a defined anion conduction pathway that opens with different open probability for separate substrate conditions. Although there are marked differences in macroscopic EAAT anion currents, the underlying single channel amplitudes are very similar among different isoforms (Torres-Salazar & Fahlke, 2007; Winter et al., 2012), indicating that the anion conduction pathway is well conserved. All EAAT anion channels exhibit a lyotropic selectivity sequence (Wadiche & Kavanaugh, 1998; Melzer et al., 2003), indicating that selectivity between anion is determined by anion dehydration rather than by association to defined binding sites. These functional data suggest a rather hydrophobic pore with low electrostatic potential.

The physiological importance of EAAT anion channels is illustrated by episodic ataxia (EA), a human genetic disease characterized by paroxysmal cerebellar incoordination. There are several genetically and clinically distinct forms of this disease, and one of them, episodic ataxia type 6, is caused by mutations in the gene encoding a glial glutamate transporter, the excitatory amino acid transporter (EAAT) 1. We examined the effects of a disease-associated point mutation, P290R, on glutamate transport, anion current as well as on the subcellular distribution of EAAT1 using heterologous expression in mammalian cells (Winter et al., 2012). P290R reduces the number of EAAT1 in the surface membrane and impairs EAAT1-mediated glutamate uptake. Cells expressing P290R EAAT1 exhibit larger anion currents than WT cells in the absence as well as in the presence of external L-glutamate, despite a lower number of mutant transporters in the surface membrane. Noise analysis revealed unaltered unitary current amplitudes, indicating that P290R modifies opening and closing, and not anion permeation through mutant EAAT1 anion channels. These findings identify gain-of-function of EAAT anion conduction as pathological process in episodic ataxia. Increased EAAT1 anion currents might modify intracellular anion concentrations and thus affect GABAergic transmission. These data illustrate possible functional roles of EAAT anion channels also under physiological conditions.

SA439

GABA transporters, GABA release and opioid dependence

E. Bagley

Pharmacology, University of Sydney, University of Sydney, NSW, Australia

Neurotransmitter transporters can affect neuronal excitability indirectly via modulation of neurotransmitter concentrations or directly via transporter currents. A physiological or pathophysiological role for transporter currents has not been described. We found that GABA transporter 1 (GAT-1) cation currents directly increased GABAergic neuronal excitability and synaptic GABA release in the periaqueductal gray (PAG) during opioid withdrawal in rodents. In contrast, GAT-1 did not indirectly alter GABA receptor responses via modulation of extracellular GABA concentrations. Notably, we found that GAT-1-induced increases in GABAergic activity contributed to many PAG-mediated signs of opioid withdrawal. Together, these data support the hypothesis that GAT-1 activity directly produces opioid withdrawal signs through direct hyperexcitation of GABAergic PAG neurons and nerve terminals, which presumably enhances GABAergic inhibition of PAG output neurons. These data provide, to the best of our knowledge, the first evidence that dysregulation of a neurotransmitter transporter current is important for the maladaptive plasticity that underlies opiate withdrawal.

Bath salts interactions with the human dopamine transporter

L.J. De Felice

Physiology and Biophysics, Virginia Commonwealth University, Richmond, VA, USA

Action potentials (APs) release dopamine (DA) via voltage gated ion channels that de-polarize the presynaptic membrane, open Ca++ channels, and increase the probability of vesicle fusion and DA release. The dopamine transporter (DAT) transports DA back into the presynaptic membrane where it is repackaged into synaptic vesicles. Presynaptic membrane depolarization is thus the trigger for neurotransmitter release. We will argue that abused drugs (such as amphetamine, AMPH, methamphetamine, METH, and certain structurally related cathinones present in bath salts) bypass the normal AP-generated DA release mechanism. Present theories to explain drug-induced DA release rely on DAT reverse transport and include AMPH-DA exchange, phosphorylation-induced efflux, channel-mode efflux, or AMPH-induced vesicular depletion. An alternative mechanism for drug-induced DA release requires a departure from the traditional model of Na-coupled transport (the fixed stoichiometry alternating access model) and proposes another model of co-transport (the flux coupled channel model). We have recorded electrical currents mediated by hDAT expressed in Xenopus laevis oocytes and HEK cells exposed to DA, METH, a known hDAT stimulant and DA releaser, mephedrone (MEPH), methylenedioxypyrovalerone (MDPV), MEPH + MDPV, or cocaine, a known hDAT inhibitor (1). DA, METH, and MEPH induce an inward depolarizing current when cells are held near rest (-60 mV), therefore acting as excitatory hDAT substrates. Structurally analogous MDPV induces an outward hyperpolarizing current under the same conditions, similar to cocaine, and therefore acts as an inhibitory non-substrate blocker. Two common components of bath salts, MEPH and MDPV, thus produce opposite effects at hDAT that are comparable to METH and cocaine, respectively. In our assay MEPH is nearly as potent as METH; however, MDPV is 35X more potent than cocaine and its effect as a blocker lasts much longer. When applied in combination, MEPH exhibits faster kinetics than MDPV; namely, the MEPH depolarizing current occurs seconds before the slower MDPV hyperpolarizing current. Bath salts are not a defined combination of drugs; however, those that contain MEPH (or a similar drug) and MDPV might be expected initially to release DA and subsequently to prevent its reuptake via hDAT. The channel mode of dopamine transporters is thus crucial to understand how AMPH-like drugs including synthetic cathinones can affect the integration of inputs to dopaminergic neurons to modify excitability, activate voltage-gated channels, and regulate synaptic signaling. Our central hypothesis states that AMPH-like drugs (including certain synthetic cathinones present in bath salts) induce depolarizing currents in excitable cells that increase the probability of Ca++ entry, vesicular fusion, and DA release from the presynaptic terminal. In addition, wherever hDAT is located (for example on the cell body), drug-induced depolarization via the channel mode of transporters may increase excitability (2). The powerful positive feedback mechanism of AMPH-like drugs on dopaminergic neurons may generalize to drugs that interact with serotonin or norepinephrine transporters. Conversely, transporter blockers such as cocaine, MDPV, or fluoxetine may have a negative feedback on endogenous or induced currents mediated via transporters, thus lowering the probability of transmitter release. The contribution of transporters to the electrical profile of neurons depends on a more complete picture of synapses than we have at present. In particular, the setting of transporters in the context of voltage-gated ion channels would be essential to understand fully the contribution of transporter channels to neurotransmitter release. However, evidence is growing that AMPH, and by inference AMPH-like drugs, may release DA via vesicle fusion mechanisms (3, 4). In summary, bath salts that contain both DA releasers (mephedrone, methylone, etc.) and a reuptake inhibitor (MDPV) act synergistically on hDAT, which may explain the powerful effect of this drug combination on bath salts abusers. We will discuss how drug interactions with transporters modify electrical signaling for nerve cell communication that is important for brain physiology and pathology.

Dorsal-ventral differences in HCN channel function and expression in hippocampus

D. Johnston[1], K. Dougherty[1] and D. Nicholson[2]

[1]Center for Learning and Memory, University of Texas at Austin, Austin, TX, USA and [2]Department of Neurological Sciences, Rush Univ. Med. Center, Chicago, IL 60612, ID, USA

The rodent hippocampus can be divided into dorsal and ventral domains based on distinct anatomical, biochemical, and behavioral phenotypes associated with each region. Recently, we explored the cellular properties of CA1 pyramidal neurons in these two regions, and found that CA1 neurons from the ventral region are intrinsically more excitable than their dorsal counterparts. Among the many possible differences in ion channel expression and function that could account for these different cellular properties, we have initially focused on the hyperpolarization-activated cation-nonselective current (Ih). Measurement of Ih using cell-attached patches along the somatodendritic axis revealed a significant distant-dependent depolarizing shift in the $V_{1/2}$ of activation for h-channels in ventral, but not dorsal neurons. Ultrastructural immuno-localization of HCN1 and HCN2 h-channel subunits revealed a similar distant-dependent shift in the HCN1/HCN2 ratio for ventral, but not dorsal neurons. These observations suggest that a shift in the expression of HCN1 and HCN2 drives functional changes in I_h for ventral neurons, and could thereby significantly alter dendritic integration in neurons from these two regions.

The cellular basis of sensory hyperexcitability in the Fmr1 knockout mouse model of Fragile X Syndrome

A. Frick[1], Y. Zhang[1], A. Bonnan[1], M. Ginger[1], I. Ferezou[2], J. Rossier[3] and B. Oostra[4]

[1]Neurocentre Magendie, INSERM U862, Bordeaux, France, [2]CNRS UPR 3293, Gif-sur-Yvette, France, [3]CNS UMR7637, Pariz, France and [4]Erasmus MC, Rotterdam, Netherlands

Increased sensitivity to sensory stimuli is a prominent feature of Fragile-X Syndrome (FXS) and other Autism Spectrum Disorders (ASD), but its underlying mechanisms are poorly understood. We found that deletion of the Fmr1 gene results in somatosensory hyper-excitability in a mouse model for FXS. Fmr1 knockout (Fmr1KO) mice required significantly less tactile information for haptic exploration, and touch-evoked whisker representations in the primary somatosensory cortex (S1) spread with increased velocity in Fmr1KO mice compared to wild-type control. At the cellular level, dendrites of S1 pyramidal neurons were hyper-excitable, facilitating the coupling of synaptic input to the generation of action potential output in these neurons. This defect was, at least in part, attributable to a dysfunction of h-channels and BKCa channels and was partially rescued by pharmacological activation of BKCa channels. These findings argue for a novel and critical role for channelopathies in the expression of sensory hyper-excitability in FXS and ASD.

Dendritic computation *in vivo*

S.L. Smith, I.T. Smith, T. Branco and M. Häusser

Wolfson Institute for Biomedical Research, University College London, London, UK

The computational power of dendrites has long been predicted using modeling approaches, but actual experimental examples of how dendrites solve computational problems are rare. We have addressed this question by performing direct patch-clamp recordings from the dendrites of pyramidal cells in mouse primary visual cortex during sensory processing. Visual stimulation triggered regenerative events in the dendrites of layer 2/3 pyramidal cells, including high-frequency bursts of dendritic spikes. These events were orientation tuned and suppressed by either hyperpolarization or intracellular NMDA receptor blockade. Both these manipulations also decreased the selectivity of subthreshold orientation tuning measured at the soma, thus linking dendritic regenerative events with somatic orientation tuning. These results suggest that dendritic spikes triggered by visual input contribute to a fundamental cortical computation: enhancing orientation selectivity in visual cortex.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA444

Sensory-evoked calcium signaling in dendrites and spines of cortical neurons *in vivo*

A. Konnerth

TU Munich, Munich, Germany

Neurons in cortical sensory regions receive modality-specific information through synapses that are located on their dendrites. The use of two-photon microscopy combined with whole-cell recordings has helped identify visually-evoked dendritic calcium signals in mouse visual cortical neurons in vivo. The calcium signals were restricted to small dendritic domains ('hotspots') and represented visual synaptic inputs that were highly-tuned for orientation and direction (Jia et al., Nature, 2010). A new variant of two-photon imaging with an improved sensitivity for fluorescence signaling and a reduced risk of phototoxicity, termed LOTOS (= low power temporal oversampling), allowed the detection of sensory-evoked calcium transients in dendritic spines of mouse neurons in the auditory (Chen et al., Nature, 2011). Individual spines on the same dendrite were functionally heterogeneous. Even neighboring spines were often tuned to different sound frequencies. In line with these observations, we found in the vibrissal cortex that stimulation of different whiskers activated distinct spines on the same dendrite (Varga et al., PNAS, 2012). Some spines were activated uniquely by single whiskers, but many spines were activated by multiple whiskers. These shared spines indicate the existence of presynaptic 'feeder' neurons that integrate and transmit activity arising from multiple whiskers. Together, our results suggest that in different cortices (visual, auditory, vibrissal), afferent sensory inputs to layer 2/3 neurons are widely distributed throughout the entire dendritic tree in a 'salt-and-pepper'-like manner and that the 'computational units' in the dendrites layer 2/3 neurons in vivo are highly tuned individual spines.

Altered spatial and temporal microvascular perfusion heterogeneity in metabolic syndrome

J. Frisbee

Physiology and Pharmacology, West Virginia University HSC, Morgantown, WV, USA and Center for Cardiovascular and Respiratory Sciences, West Virginia University HSC, Morgantown, WV, USA

A key clinical outcome for non-atherosclerotic peripheral vascular disease (PVD) in patients is a progressive decay in skeletal muscle performance and its ability to resist fatigue with elevated metabolic demand. This study builds on previous work to evaluate in situ arteriolar hemodynamics in cremaster muscle of obese Zucker rats (OZR) model of the metabolic syndrome, manifesting a non-atherosclerotic PVD, to integrate existing knowledge into a greater understanding of impaired skeletal muscle perfusion and performance. In OZR cremaster muscle, perfusion distribution at microvascular bifurcations (γ) was consistently more heterogeneous than in controls. However, while consistent, the underlying mechanistic contributors were spatially divergent as altered adrenergic constriction was the major contributor to altered γ at proximal microvascular bifurcations, with a steady decay with distance, while endothelial dysfunction was a stronger contributor in distal bifurcations with no discernible role proximally. Using measured values of γ, simulations predict that successive alterations to γ in OZR caused more heterogeneous perfusion distribution in distal arterioles than in controls; an effect that could only be rectified by combined adrenoreceptor blockade and improvements to endothelial dysfunction. To minimize this negative outcome in spatial perfusion heterogeneity, a likely compensatory mechanism against an increased γ should be an increased temporal switching at arteriolar bifurcations to minimize downstream perfusion deficits. Using the identical in situ cremaster muscle preparation, we determined that temporal activity (the cumulative sum of absolute differences between successive values of γ, taken every 20 seconds) was lower in OZR than in control animals, and this difference was present in both proximal (1A-2A) and distal (3A-4A) arteriolar bifurcations. While adrenoreceptor blockade (phentolamine) improved temporal activity in 1A-2A arteriolar bifurcations in OZR, this was without impact in the distal microcirculation, where only interventions against oxidant stress (TEMPOL) and thromboxane A2 activity (SQ-29548) were effective. Analysis of the attractor for γ indicated that it was not only elevated in OZR as compared to LZR, but also exhibited severe reductions in range. Taken together, these results suggesting that the ability of the microcirculation to respond to any imposed physiological or pathological challenge becomes highly restricted with metabolic syndrome, and may represent the major contributors to the manifestation of poor muscle performance at this age in OZR.

The role of pericytes in microvascular network pattern formation

W.L. Murfee

Biomedical Engineering, Tulane University, New Orleans, LA, USA

Quantitative approaches for studying the microcirculation include computational methods and integrative experimental models. This presentation will provide examples of applying both approaches to better understanding the causes and effects of microvascular network pattern formation. The first objective will be to highlight the use of a computational method for gaining new insight into the relationship between network patterns and resistance in hypertension. Microvascular rarefaction, defined by a loss of vessels, is a common characteristic of hypertension and has been linked to elevated microvascular resistance. However, vessel loss in mesenteric microvascular networks from adult spontaneously hyperten-

sive rats (SHRs) versus age-matched normotensive Wistar-Kyoto (WKY) controls is accompanied by an increase in low resistance arterial-venule shunts. Using a computational model that can account for intact network patterns, the total resistances were compared in SHR versus WKY networks. For simulations with uniform vessel diameter and with the diameters based on reported intra-vital measurements, SHR resistance was not increased compared to the WKY level. This result challenges the paradigm that microvascular networks experience increased resistance during hypertension. Still, a question remains – What causes the vessel loss and pattern alterations in the SHR? An answer might be vascular pericytes. SHR networks also display altered pericyte expression of neuron-glia antigen 2 (NG2) implicating them as a critical cell type. The second objective of the presentation will be to introduce the rat mesentery culture model as a novel experimental tool for determining the effect of NG2 inhibition on microvascular network growth. After 3 days in culture with minimum essential media, Wistar mesenteric microvascular networks remain viable and intact. More importantly, growth factor induced endothelial cell sprouting can be inhibited by antibody blocking of NG2 on pericytes. This result confirms the importance of NG2 as a functional regulator of capillary sprouting and establishes the rat mesentery culture model as a novel tool for mechanistic studies investigating pericyte-endothelial cell interactions at specific locations within a microvascular network. Overall, the use of computational modelling and the rat mesentery culture model in these studies emphasizes the value of integrating a quantitative and systems level perspective in microvascular research.

Insights from numerical simulations of brain blood flow regulation in large anatomical networks

S. Lorthois

IMFT, CNRS, Toulouse, France

Blood micro-circulation plays a central role in the local adaptation of cerebral blood flow to neural activity (neuro-vascular coupling). A growing body of evidence indicates that neurons, glia, and cerebral blood vessels, acting as an integrated unit, have a crucial role in mediating the activation-induced changes in blood flow. In particular, the smooth muscle cells surrounding the arterioles, and possibly pericytes, at capillary level, convert the bio-chemical signals that originate from this integrated unit into changes in vascular diameter, thus regulating blood flow by modulating vascular resistance [1].
However, the relative role of arterioles and capillaries in the control of cerebral blood flow is still controversial [1]. In particular, it is at present not clear whether the capillary dilatation experimentally observed in vivo by several groups is a passive consequence of upstream arteriolar dilatation via an alteration in perfusion pressure or the result of an active regulation of the capillary diameter via contraction/relaxation of pericytes [1].
Answering this question is of importance in the context of functional neuroimaging. The spatial resolution and specificity of hemodynamically based functional imaging techniques (including fMRI and PET) are indeed bound to the density and localization of the blood flow regulating structures [2].
However, using experimental means for that purpose is extremely challenging. For example, the penetration depth of the most recent intravital two-photon microscopy techniques (typically ~500 μm) does neither allow to investigate the cortical layers of highest capillary density, which are located approximately in the middle third of the cortex [3] nor those where the fastest capillary dilation occurs [4].
By contrast, several authors [1,5] have pointed out that modelling using anatomically accurate representations of the intracortical vascular network allows a better and more quantitative understanding of cerebral blood flow control. In particular, such an approach can be valuable for generating predictions as to the likely impact of pericyte-mediated capillary diameter regulation [1].
Our group has recently performed the first numerical simulations of blood flow in an anatomically accurate large human intra-cortical vascular network (~ 10000 segments), using a 1D non-linear model taking into account the complex rheological properties of blood flow in microcirculation (i.e. Fahraeus, Fahraeus-Lindquist and phase separation effects) [6]. This model predicts blood pressure, blood flow and hematocrit distributions, volumes of functional vascular territories, regional flow at local, voxel and network scales, etc.
Using this approach, we have studied the flow re-organizations induced by arteriolar vasodilations, highlighting the hemodynamic component of various functional neuroimaging techniques [7].
In the present paper, the variations in cerebral blood flow induced by global or localized capillary vasodilations are studied and compared to these previous results, demonstrating that pericyte-mediated regulation of blood flow at capillary level would be efficient for neuro-vascular coupling. By contrast to a regulation situated at the level of arterioles [7], the changes in blood volume can be highly localized in space, with the potential to be as close as possible of areas of neuronal activation. However, the changes in blood flow are much more diffuse. This imposes limits on the ultimate spatial resolution of hemodynamically based brain functional imaging techniques, whatever the localization of the blood flow regulating structures.

The spatio-temporal dynamics of vascular plexus regeneration are related to vessel function

M. Machado[1], M. Watson[3], A. Devlin[2], M. Chaplain[4], S. McDougall[3] and C. Mitchell[2]

[1]MVRL, University of Bristol, Bristol, UK, [2]CMB, University of Ulster at Coleraine, Coleraine, UK, [3]Institute of Petroleum Engineering, Heriot-Watt University, Edinburgh, UK and [4]Division of Mathematics, University of Dundee, Dundee, UK

The structure of the microvascular network within the murine *panniculus carnosus* is highly anisotropic and adapted to the functional requirements of the tissue. To assess the rate of wound closure and functional characteristics of the regenerating vascular plexus, dorsal skinfold chambers (dsc) were implanted in adult mice enabling the use of intravital microscopy. As a result of heat-induced injury to the tissue, a non-perfused area defined as wound was created. Three days after wounding, vasodilatation of the surviving vessel segments was noted even in more distal areas of the plexus, with a peak in vessel junction density at day 6 (indicative of the period of active sprouting), and partial recovery of functional vessel density by day 9.

Having established a longitudinal model of wound healing-induced angiogenesis, we sought to test the influence of different parameters in the progression of blood vessel growth. TNP-470 was the first anti-angiogenic agent to undergo clinical trials in human tumours. The main complication of anti-angiogenic therapy for tumours is its unavoidable effect on physiological processes such as wound healing. TNP-470 covalently binds and inhibits the metalloprotease methyonine aminopeptidase metAP-2 (Sin *et al.*, 1997), which is enriched in endothelial cells, effectively arresting the cell cycle. Injection of TNP-470 led to a significant delay in wound closure with both the extent of vessel sprouting and recovery of tissue perfusion inhibited compared to vehicle-injected mice. Thus, in this experimental model, increase in functional vessel density depends upon endothelial cell proliferation (Machado *et al.*, 2011).

Blind-ended vessels (BEVs) at the leading edge of an expanding vascular plexus were recognized as major regulators of the structure of the developing network (Guerreiro-Lucas *et al.*, 2008). Plasma leakage into the surrounding extracellular matrix occurring from BEVs could play an important role in preparing hypoxic tissue for vascular invasion. As such, plasma flux across the vessel wall was quantitated through the use on *in vivo* Fluorescence Recovery After Photobleaching (FRAP). Determination of time elapsed from bleaching until recovery of fluorescence intensity to half of baseline average ($t_{1/2}$) revealed that the permeability of newly formed vessel segments (both flowing and blind-ended) is greater than that of pre-existing vessels between days 5-7 after injury. Furthermore, TNP-470 reduces macromolecular flux across the vessel wall of BEVs at the leading edge of the advancing vascular plexus, while increased FITC-dextran leakage was observed from pre-existing vessels after treatment with TNP-470 ($p<0.05$), consistent with induction of transient vascular damage, (Machado & Mitchell, 2011). This evidence contradicts previous reports where quiescent endothelium is not affected by TNP-470 (Kruger & Figg, 2000). Using *in vivo* FRAP in the dsc, these studies demonstrate the relationship between temporal changes in microvascular macromolecular flux and the morphology of maturing vascular segments. The combination of techniques used to characterize the morphology and function of the newly-formed blood vessels in this experimental model provided spatially and temporally resolved data, which is amenable for use within mathematical modeling approaches. The predictive power of these data-driven models will enable us to test for unwanted side effects of anti-angiogenic drugs, such as the increased leakiness of pre-existing vasculature.

Insights from structure based imaging, analysis and computational modelling of coronary microcirculation

N. Smith[1], A. Goyal[1], T. Sochi[1], J. Spaan[2], M. Siebes[2], J. van den Wijngaard[2] and J. Lee[1]

[1]King's College London, London, UK and [2]Medical Physics, Amsterdam Medical Center, Amsterdam, Netherlands

Coronary microcirculatory flow is governed by a number of determinants including network anatomy, systemic afterload and the mechanical interaction with the myocardium throughout the cardiac cycle. The range of spatial scales and multi-physics nature of coronary perfusion highlights a need for a multi-scale framework that captures the relevant details at each level of the network. Using a data driven structural based approach we have developed a set of novel methods to reconstruct three-dimensional coronary vasculature from images, comprised of two distinct sets of data – fluorescent microsphere beads and anatomically vasculature. Current state-of-the-art radii estimation methods and a model-based method were applied on whole-organ porcine data that was automatically reconstructed. Using this anatomical model blood flow simulations were performed to obtain blood flow rate, calculated using the conductance and pressure drop across each branch in the tree throughout the whole vasculature. The results from this blood flow simulation were compared to regional microsphere perfusion distribution.

At each branch in the arterial tree, the number of microspheres that passed through it in the vasculature was counted. Shortest path tracing also revealed the main source coronaries for every branch in the arterial tree and the myocardial perfusion regions of these main coronaries. The regional microsphere distribution (number of microspheres counted going through a branch, normalized by the total number of microspheres counted in the entire perfused region of myocardium) was compared to the regional flow (flow rate in a branch normalized by the total flow rate in the root artery). To analyze the discrepancy observed between the microsphere perfusion and flow model, we studied the distribution of microspheres at

bifurcations. Using this data we have constructed a model of this error parameterised by the branching angle and daughter-to-parent ratio of the vessel cross-sectional area is shown to more accurately predict the biased distribution of the microspheres. Incorporating the disproportionate microsphere distribution model at bifurcating segments with the largest branch angles, ranging from 100- 120 degrees, reduced the error from 24 to 7 percent error in between the fraction of flow predicted by the model and the fraction of microspheres.

Role of tight junction claudins in biological systems – more than a simple paracellular barrier in inflammation and metabolism

S. Tsukita

Laboratory of Biological Science Graduate School of Frontier Biosciences and Graduate School of Medicine, Osaka University, 2-2, Yamadaoka, Suita, Japan

The tight junction (TJ) system is primarily responsible for establishing the paracellular barrier function of epithelial cell sheets. The TJ is a supramolecular complex containing transmembrane proteins associated with membrane-scaffolding proteins such as ZO-1/2 and cingulin that allows the dynamic regulation of ion and solute passage across the paracellular space. Among the TJ transmembrane proteins, claudins are specifically required to form the TJ strands that organize the paracellular barrier structure. The multi-gene claudin family has at least 27 members in human and mouse. Although claudins are paracellular barrier-forming proteins, certain “ion leaky” claudins specify which ions can cross the barrier. A remarkable characteristic of claudin family proteins is their distinct tissue-dependent expression patterns. In our laboratory, some claudins such as claudins 2,15,18 have recently been intensively studied with regard to their biological roles in processes such as inflammation and nutrient absorption. These studies highlight the functions of claudin beyond that of a simple barrier.

Elucidating the molecular organization of tight junction strands and design of claudin-modulators

J. Piontek

Leibniz-Institut für Molekulare Pharmakologie; Institut für klinische Physiologie, Charité, Berlin, Germany

The paracellular barrier in epithelia and endothelia is formed by tight junctions (TJ). They limit and regulate the paracellular permeation of ions, solutes and proteins. The barrier properties of TJs in different tissues are mainly determined by the claudin composition of the heteropolymeric TJ-strands. To analyze the molecular organization of TJ, these strands were reconstituted by claudin-transfection of TJ-free HEK293-cells. A single claudin-construct was expressed to obtain defined homomeric TJ-strands. In addition, another claudin subtype or a member of the TJ-associated marvel domain protein family was expressed to obtain defined heteromeric TJ-strands. The ability to form strands and their morphology was investigated by freeze fracture electron microscopy or single molecule fluorescence nanoscopy. The barrier function of the TJ-strands was demonstrated by tracer exclusion imaging. cis-Interactions of claudin molecules were investigated by cellular fluorescence resonance energy transfer (FRET)- and native PAGE. trans-Interactions were detected by confocal cell-cell contact enrichment scanning. The mobility of claudins in the membrane was measured by fluorescence recovery after photobleaching (FRAP). This approach was used to characterize heterophilic compatibility of claudins. In addition, to elucidate mechanistic details of the claudin assembly, the blood brain barrier relevant Cld5 and Cld3 that differ in assembly properties were analyzed in more detail. Generation and investigation of Cld3/Cld5 chimeric mutants revealed protein segments and residues differentially involved in the assembly of claudin oligomers and TJ-strands. Futhermore, the domain III of Clostridium perfringens enterotoxin (cCPE), a high affinity ligand of a subset of claudins was used as a probe to gain information about the structure of the extracellular loop 2 of classic claudins. The experimental data was combined with schematic and molecular homology modeling of Cld3 and Cld5. The results provide novel molecular insights into subtype-specific assembly of classic claudins, paracellular barriers and the potential of pharmacological claudin-modulation, e.g. for paracellular drug delivery or treatment of claudin-overexpressing tumors.

SA452

Identifying proteins and protein networks of the tight junction

J. Anderson and C.M. Van Itallie

National Institutes of Health, Bethesda, MD, USA

The proteins and functional protein networks of the tight junction remain incompletely defined. Among the currently known proteins are barrier forming proteins like occludin and the claudin family, scaffolding proteins like ZO-1 and some cytoskeletal, signaling and cell polarity proteins. To define a more complete list of proteins and investigate their functional

implications, we identified the proteins which are within molecular dimensions of ZO-1 by fusing biotin ligase to either its N- or C-terminus, expressing these fusion proteins in MDCK epithelial cells and purifying and identifying the resulting biotinylated proteins by mass spectrometry. Out of a predicted proteome of ≈ 9000 we identified more than 300 proteins tagged by biotin ligase fused to ZO-1, with both identical and distinct proteins near the N- and C- terminal ends. Those proximal to the N-terminus were enriched in transmembrane tight junction proteins and those proximal to the C-terminus were enriched in cytoskeletal proteins. We also identified many unexpected, but easily rationalized proteins. In addition, functional networks of interacting proteins were tagged, such as the basolateral but not apical polarity network. These results provide a rich inventory of proteins and potential novel insights into functions and protein networks that should catalyze further understanding of tight junction biology. This approach is being extended to identify proteins which are near occludin and claudins with the goal of defining subjunctional protein compartments.

Patch clamp recordings reveal paracellular claudin-2 channels

C. Weber

Pathology, The University of Chicago, Chicago, IL, IL, USA

There are a large number of intestinal disorders in which tight junction barrier defects are associated with changes in the expression and/or localization of tight junction proteins. In particular, claudin-2 has been shown to be upregulated in a number of disease states, including inflammatory bowel disease. Expression of claudin-2 has been demonstrated to increase paracellular Na^+ permeability without increasing permeability to large molecules. This finding has contributed to the hypothesis that claudin-2 forms paracellular size and charge selective pore-like structures. However, available measures to study barrier function of epithelial monolayers cannot resolve function of individual pores. To overcome this limitation, patch clamp recordings were used to define claudin-2 function at a single channel level.
Tight junction patch clamp recordings reveal single claudin-2 channel openings. Claudin-2 expression reduces global measures of transepithelial resistance and induces a corresponding increase in the frequency, but not size of claudin-2 opening events detected in patch clamp recordings. Opening events were not detectable when electrodes were sealed on apical cell membranes away from tight junctions. Ion substitution analyses demonstrate that claudin-2 openings are cation selective and permeable to methylamine$^+$ (radius 1.9 Å), but have low permeability to tetramethylammonium$^+$ (radius 2.8 Å). Claudin-2 channel openings are blocked by cysteine derivatization of I66, a residue within the first extracellular loop of claudin-2, known to be an important determinant of claudin-2 pore properties. Similarly application of lanthanum, a known claudin-2 blocker blocks all single channel openings. These data show that claudin-2 size and charge selectivity are explained by the average behavior of a population of claudin-2 channels present in the tight junction. Furthermore, these data suggest frequency and duration of tight junction channel openings as potential mechanism whereby tight junction barrier function may be regulated in health and disease.

Towards understanding tight junction functions and signalling

M. Balda

University College London, London, UK

Tight junctions are key componet of cell-cell junctional complexes in epithelial and endothelial cells. Tight junction proteins participate in the control of the diffusion of molecules through the paracellular pathway, act as an intramembrane diffusion barrier for lipids between the apical and basolateral cell surface domains, as well as function in the regulation of cell proliferation and gene expression. We have identified and characterized several TJ-associated signalling complexes that contain different types of signalling proteins, such as ZONAB, a ZO-1-interacting nucleic acid binding protein, RhoGTPase activators such as GEF-H1 and p114RhoGEF, and the Rho GAP SH3BP1. Results will be discussed that disclose further molecular mechanisms on how tight junctions regulate paracellular permeability, cell proliferation and survival, as well as transcriptional and postranscriptonal modes of gene expression.

Maternal obesity and the developmental programming of hypertension; a role for Leptin

P.D. Taylor

Women's Health, King's College London, London, UK

The prevalence of maternal obesity has more than doubled in the past two decades with approximately 1 in 5 UK pregnant women now obese [1]. Maternal obesity and excessive gestational weight gain (GWG) constitute some of the most common obstetric risk factors and have direct implications for pregnancy outcome [2]. However, recent evidence suggests that maternal obesity may also have deleterious consequences for the cardiovascular health of the next generation. Mother-child cohort studies have established that both pre-pregnancy BMI and GWG are independently associated with cardio-metabolic risk factors in young adult offspring, including systolic and diastolic blood pressure [3, 4]. Animal models in sheep and non-human primates provide further evidence for the influence of maternal obesity on offspring cardiovascular function, whilst our recent studies in rodents have shown that fetal exposure to the metabolic milieu of maternal obesity may permanently

change the regulatory pathways in the hypothalamus that contribute to cardiovascular homeostasis.
Leptin plays an important role in the central control of appetite, and is also involved in activation of efferent sympathetic pathways to both thermogenic and non-thermogenic tissues, such as the kidney, and is therefore implicated in obesity-related hypertension. Leptin is also thought to have a neurotrophic role in the development of the hypothalamus and we have recently reported that altered neonatal leptin profiles secondary to maternal obesity were associated with evidence of permanently altered hypothalamic structure and function. Hyperphagia and increased adiposity in the adult offspring of obese rodents is associated with region specific hypothalamic leptin resistance in the appetite regulatory pathways of the arcuate nucleus[5]. We have recently reported compelling evidence from our rodent model that maternal obesity confers persistent sympathoexcitatory hyper-responsiveness and hypertension acquired in the early stages of development. Juvenile offspring develop hypertension as early as 30 days of age and, importantly, prior to the onset of obesity. Hypertension in the offspring of obese rats results from persistent sympathoexcitatory hyper-responsiveness[6] with enhanced cardiovascular stress reactivity, an increase in low/high frequency ratio of heart rate variability (HRV), and increased pressor response to exogenous leptin, all evidence of increased sympathetic tone. Disturbed sympathetic control of blood pressure has not previously been reported as a consequence of maternal obesity. The baroreflex response was also abnormal in OffOb rats (90days) and may also represent a primary programmed defect secondary to maternal obesity.
To investigate the role of neonatal hyperleptinaemia in offspring cardiovascular dysfunction, we have treated naive rats with exogenous leptin on postnatal days 9-14. At 1 month of age leptin-treated rats displayed increased mean arterial pressure (MAP) compared to saline treated controls which continued into adulthood. These data provide proof of principle that hyperleptinaemia during a critical window of hypothalamic development may directly lead to adulthood hypertension.
These data add to increasing evidence for developmental plasticity in the central efferent pathways of the autonomic nervous system, and further implicates a central role for an acquired selective leptin resistance and 'hardwiring' of the developing hypothalamus for a hyperphagic and hypertensive offspring phenotype in offspring of obese rodents. Insight from these animal models raises the possibility that early life exposure to leptin in humans leads to early onset essential hypertension. On-going mother-child cohort and intervention studies in obese pregnant women provide a unique opportunity to address associations between maternal obesity and offspring cardiovascular function.

Epigenetic mechanisms in the developmental programming of cardiovascular and metabolic disease

T. Plosch

University Medical Center Groningen, Groningen, Netherlands

An overwhelming body of evidence links fetal (mal)nutrition to the development of chronic diseases at adult age (DOHaD hypothesis, Developmental Origins of Health and Disease). Several explanations for the various observed facets of the long-term consequences of fetal (under)nutrition are currently under investigation.
In recent papers, epigenetic mechanisms like DNA methylation or histone modifications have been proposed to be involved in metabolic programming: CpG islands, CG-dinucleotide-rich regions in the promoter of a gene, have been shown to be of crucial importance for the transcriptional activity of particular promoters. In general, transcription of a gene is blocked when the CpG island is methylated. A second layer of complexity is added by the fact that methylated areas of DNA attract methyl-DNA binding proteins and acquire histone modifications which also affect the accessibility of the DNA for transcription. Together, the interaction of DNA methylation and histone modification can regulate the activity of a DNA region. New technologies (pyrosequencing, next generation sequencing) now enable us to measure DNA methylation and the active/silent areas of chromatin in a genome-wide way and correlate it with physiological observations.
Embryonic development proceeds as a complex set of interdependent and precisely integrated biological programmes, initiated by selective transcription of specific genes at specific points of time and regulated by a controlled maternal supply of nutrients. With the current state of knowledge of molecular regulation of cholesterol and lipid metabolism, it is possible to generate a network of metabolic events in the embryo and the fetus that may underlie programming. Nuclear receptors (PPARs, LXRs, FXR) provide the vehicles through which nutrients interact with the (epi)genome. Expression of these nuclear receptors is at least partially under control of CpG islands.
Disturbances in this complex network of interactions represent key events in metabolic programming of insulin resistance, hyperlipidemia and cardiovascular disease and are the focus of my work. I will discuss some of the early epigenetic modifications we observed in animal models and human samples and try to link them to metabolic and cardiovascular disease in later life.

Early life stress-induced mechanisms of cardiovascular disease

J.S. Pollock, C. De Miguel, D.H. Ho, D.M. Pollock and A.S. Loria

Experimental Medicine, Georgia Regents University, Augusta, GA, USA

Maternal separation (MatSep) is a model of behavioral stress during early life in rodents. This model of early life stress has been extensively studied with respect to behavioral outcomes in adulthood. MatSep induces a pro-anxiety phenotype in adult rats. We hypothesized that MatSep may also promote vascular dysfunction and/or overt cardiovascular disease. MatSep was performed in male Wistar Kyoto rats 3 hs/day from day 2 to 14 of life. Non-separated littermate rats (NS) were used as control. For all experiments described with ex vivo tissues, we utilized intraperitoneal injection of 65mg/kg sodium pentobarbital to terminate the rats for dissection of tissues. We reported that MatSep induces an exaggerated angiotensin II (AngII)-induced aortic constriction ex vivo in adult male rats. The exaggerated AngII-mediated aortic constriction was specific to the AngII pathway because other vasoconstrictor mediators (ET-1, phenylephrine, KCl) did not elicit an exaggerated response in the MatSep rats. We found that MatSep induces a dysfunction in AngII-mediated signaling specifically in the endothelium, such that NOS activation was impaired and NO buffering was reduced. AngII receptors, AT1 and AT2, function was determined. Vascular AT2 activation was impaired, while AT1 appeared to be intact. Moreover, vascular AT2 expression was significantly reduced. AT1 receptor and other known AngII pathway genes were shown to have similar expression levels in MatSep and NS rats. We hypothesized that MatSep would induce an AngII-sensitive phenotype in vivo. We anesthetized rats with 2% isoflurane gas by inhalation and inserted radiotelemetry devices to monitor blood pressure chronically. In vivo, MatSep rats elicit exacerbated AngII-induced hypertension mediated via a loss of NO buffering capacity as elucidated with L-NAME (NOS inhibitor) in the drinking water. AngII infusion induced a significant increase in AT1 receptor expression in the renal cortex of MatSep rats, while in NS rats a decrease in AT1 receptor expression was found. AngII infusion in the MatSep rats enhanced increased T cell and macrophage infiltration to the endothelium and the peri-vascular adventitia of the aorta; as well as T cell infiltration was shown to be exaggerated in the renal cortex by immunohistochemical techniques. Remarkably, AngII-induced renal damage was exaggerated exclusively in the interstitial arteries of MatSep rats by histological analyses. These data indicate that MatSep sensitizes AngII responses via increased activation of AT1 receptors, leading to an increased hemodynamic response associated with an enhanced T cell activation. To further elucidate the immune response of the MatSep rats, we exposed NS and MatSep rats to an acute (12 hr) exposure of lipopolysaccharide (LPS) injected intraperitoneally. No differences were found in the number of circulating or renal T cells at baseline or in LPS-treated rats. Renal tissue from LPS-treated MatSep rats showed a 4 to 16 fold increase in levels of cytokines (IL-16, CCL3, CCL4, IFNg), chemokine receptors (CCR3, CCR4, CXCR4) and activation markers (CD40, CD40Ig) compared to LPS-treated NS rats indicating that MatSep sensitizes T cell activation. These results indicate that MatSep enhances pro-inflammatory activation of circulating and renal T cells, which most likely leads to promotion of pathological cardiovascular responses. Our findings provide new insights in the mechanisms of developmental programming of cardiovascular disease and new risk factors associated to an adverse postnatal environment.

The roles of 11β-hydroxysteroid dehydrogenase type 2 in placenta and fetus in developmental programming

E. Cottrell[1], M.C. Holmes[2], J.R. Seckl[2] and C.S. Wyrwoll[3]

[1]Institute of Human Development, University of Manchester, Manchester, UK, [2]University/BHF Centre for Cardiovascular Science, University of Edinburgh, Edinburgh, UK and [3]The University of Western Australia, Perth, WA, Australia

Fetal growth restriction (FGR), reflective of an adverse intrauterine environment, confers a significantly increased risk of perinatal mortality and morbidity. In addition, low birth weight associates with adult diseases including hypertension, metabolic dysfunction and behavioural disorders. Glucocorticoids are critical for fetal development, however exposure of the fetus to excess glucocorticoids reduces fetal growth and can permanently alter organ structure and function, predisposing to disease in later life.

Fetal glucocorticoid exposure is regulated, at least in part, by the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which catalyzes the intracellular inactivation of glucocorticoids. This enzyme is highly expressed within the placenta at the maternal-fetal interface, limiting passage of glucocorticoids to the fetus. Expression of 11β-HSD2 is also high in fetal tissues, particularly within the developing central nervous system (CNS). Down-regulation or genetic deficiency of placental 11β-HSD2 is associated with significant reductions in fetal growth and birth weight, and programmed outcomes in adulthood.

We have shown that in addition to reducing the passage of glucocorticoids, 11β-HSD2 plays a key role in regulating placental function through modulation of local glucocorticoid levels, affecting placental vascularization, blood flow and transport capacity. Endogenous placental 11β-HSD2 activity can also be modulated by maternal stressors (such as poor diet), suggesting that regulation of glucocorticoid metabolism may play a part in feto-placental adaptation to adverse conditions. The question still remains as to whether it is placental or fetal 11β-HSD2 that are key to subsequent programmed outcomes. A recently developed knockout of 11β-HSD2 specifically within

the CNS during development suggests that neural 11β-HSD2 does indeed have a role in protecting the developing brain and thus determining adult behavioural outcomes. This may prove to be a partial role (additive to that of 11β-HSD2 in the placenta), as the phenotype appears more subtle than the global 11β-HSD2 knockout. Thus, alterations in 11β-HSD2 within both fetal and placental tissues affects growth and development during the perinatal period, and influences the life-long health of an individual.

Studies were supported by a Wellcome Trust project grant (to M.C.H. and J.R.S.) and a Human Frontier Science Program grant (RGP0039/2006-C) to J.R.S.

SA459

Sex differences and programming of hypertension

B.T. Alexander

Physiology, Univ Miss Med Ctr, Jackson, MS, USA

Hypertension is a multi-factorial disorder thought to result from both genetic and environmental factors. Numerous epidemiological studies report an association between birth weight and blood pressure. This association is observed in a variety of populations from around the world and is further supported as elevations in blood pressure are also found in low birth weight children Thus, the inverse relationship between birth weight and blood pressure suggests that factors present in the fetal environment which affect fetal growth are responsible for the developmental programming of blood pressure control. Recent experimental studies suggest that developmental programming occurs in response to adverse environmental influences during fetal life resulting in permanent adaptive responses that lead to structural and physiological alterations and the subsequent development of cardiovascular disease and hypertension. Sex differences in response to fetal insult are observed in many animal models of developmental programming with phenotypic outcome linked to the severity of the insult. In general, phenotypic outcome is more severe in male offspring relative to females (1). Although the exact mechanisms that mediate the sexual dimorphism in programmed blood pressure are unclear, experimental studies suggest that sex-specific programming of blood pressure involves a key role for the kidney (1), the renin angiotensin system (2), oxidative stress (3), and sex steroids (4). Whether a sex difference in blood pressure is present in low birth weight men relative to low birth weight women has not been clearly established. However, one study indicates that blood pressure is higher in low birth weight boys relative to low birth weight girls during childhood (5). Other studies indicate that men demonstrate a strong association between birth weight and blood pressure in young adulthood (6), whereas hypertension is not present until age 60 in low birth weight women (7). Thus, these studies suggest that the association between birth weight and blood pressure amplifies with age. Moreover, age may adversely impact the protective role of the female sex on programming of later chronic health. It is well established that aging is a critical mediator of age-related increases in blood pressure. Yet, few experimental studies have examined the impact of aging on sex differences in programmed hypertension. Thus, susceptibility to developmental programming of hypertension is sex-specific. However, age-dependent changes may serve as a secondary influence following fetal insult implicating a need for further studies to investigate the impact and the mechanisms involved in age-dependent increased cardiovascular risk in low birth weight men and women.

Heterothermy in Afrotropical birds: phylogenetic and ecological patterns

A. McKechnie

University of Pretoria, Hatfield, South Africa

In comparison to mammals, relatively little is known about the ecology and phylogenetic distribution of heterothermy in birds. Reviews of avian hetereothermy have not so far revealed any clear links with climatic variables, but instead suggest heterothermy is most pronounced in phylogenetically older taxa that feed on spatially and temporally unpredictable diets such as nectar, aerial insects, or fruit. Africa's avifauna offers rich opportunities to investigate phylogenetic and ecological correlates of heterothermy, and here I review recent work in this area.

Mousebirds (Coliiformes) are a phylogenetically ancient order endemic to the Afrotropics, and have long been considered one of the avian taxa in which torpor is most pronounced. However, work on both captive and free-ranging mousebirds reveals that the ecological significance of torpor in this group needs to be viewed in the context of its interaction with communal roosting behaviour; whereas mousebirds readily enter torpor when housed individually, when roosting communally they maintain body temperatures (T_b) similar to typical avian normothermic values. Torpor is probably rare in wild mousebirds. Two other non-passerine taxa whose phylogenetic position, body mass and ecological traits suggest they might have evolved the capacity for pronounced heterothermy are barbets (Piciformes: Lybiidae) and small owls (Strigidae). Two species of barbets held in outdoor aviaries in mid-winter

showed small decreases in rest-phase T_b, but not the large reductions characteristic of torpor. In a study of thermoregulation in two small owl species in the Kalahari Desert of southern Africa, free-ranging African Scops-owls (*Otus senegalensis*) regularly reduced skin temperature (T_{skin}) by up to 8.6 °C below normothermic levels, but Pearl-spotted Owlets (*Glaucidium perlatum*) remained normothermic throughout the study period. These findings emphasise the variation in heterothermy that can exist in related species at a single site.

Patterns of heterothermy can also vary substantially within species. Among Freckled Nightjars (*Caprimulgus tristigma granosus*) in the more mesic eastern part of southern Africa, torpor was used frequently by some individuals, but was not correlated with lunar phase. In contrast, torpor in conspecifics (*C. t. lentiginous*) at a desert site was strongly linked to lunar cycles, becoming progressively deeper around new moon and shallower around full moon. These intraspecific differences likely reflect variation between sites in terms of both aridity and rainfall seasonality.

In contrast to some phylogenetically older orders, passerines appear to possess a very limited capacity for torpor. Laboratory data for a small granivorous finch from the southern African arid zone supports this view, with only small decreases in T_b occurring during periods of restricted energy supply. Body temperatures approaching those associated with deep torpor have been reported in sunbirds (Nectariniidae), although the relationship between metabolic rate, T_b and air temperature in these cases suggest a modified form of shallow hypothermia, rather than classic torpor.

The overall picture that emerges from studies of avian heterothermy is that many birds that *a priori* would seem good candidates to use pronounced torpor and/or hibernation apparently do not do so. One key factor that may select against torpor use is predation risk; the lethargic, non-responsive state characteristic of torpor likely significantly increases the risk of predation for many species. The notion that predation risk is a major evolutionary determinant of avian heterothermy is supported by recent findings that African Green-pigeons (*Treron calvus*) apparently do not enter torpor, whereas an ecologically similar species restricted to an island with no native predators does. Columbid birds, on account of their spectacular diversification on islands, potentially represent a very useful model taxon for testing hypotheses regarding the role of predation risk in the evolution of torpor in birds.

Mechanisms of mitochondrial metabolic suppression in hibernation

J.F. Staples

Biology, University of Western Ontario, London, ON, Canada

In winter mammalian hibernators, such as the 13-lined ground squirrel (*Ictidomys tridecemlineatus*), enter a state of torpor where metabolic rate is suppressed by ca. 90%, and body temperature (T_b) subsequently declines towards freezing. These changes are fully reversed during arousals, which occur spontaneously every 5-14 days throughout the winter. Arousals return animals to full euthermia for ca. 1 day before they enter another bout of torpor. This cycle is apparently driven by endogenous signals, and offers an excellent natural model to study plasticity of many physiological functions, including mechanisms of metabolic.

The reversible suppression of whole-animal metabolism in hibernation is mirrored by some aspects of mitochondrial oxidative phosphorylation. In liver mitochondria isolated from torpid animals, state 3 (phosphorylating) respiration, fueled by succinate oxidation, is ca. 70% lower than in euthermic animals, even when measured at the same *in vitro* temperature (37ºC)[1]. Torpid suppression of mitochondrial respiration may conserve endogenous fuels and minimize damage by ROS, but it is not evident in all tissues, including cardiac muscle and forebrain. Moreover this suppression depends on several factors, including oxidative substrate and *in vitro* assay temperature. For example, in mitochondria isolated from skeletal muscle, respiration is suppressed in torpor by ca. 35%, but only with succinate as substrate, and only when measured at 37ºC[2]. Although not universal, the plasticity of oxidative phosphorylation seen in some hibernator tissues provides valuable information about the regulation of mitochondrial metabolism. In liver mitochondria suppression of state 3 respiration occurs early during entrance into torpor, declining by 70% within the short time it takes for T_b to fall from 37ºC to 30ºC[3]. Conversely, reversal of this suppression during arousal occurs only gradually, and even after T_b rises from 5ºC to 30ºC, respiration is only ca. 50% of values from fully aroused, euthermic animals[4]. This "fast in, slow out" pattern suggests that acute and temperature-sensitive mechanisms are responsible for the reversible suppression of mitochondrial metabolism, and our recent research seeks such mechanisms.

Mitochondrial membranes are remodeled during entrance and arousal, with changes in both phospholipid classes and fatty-acyl chain saturation. These membrane changes, however, are transient and do not correlate with mitochondrial respiration[5]. In torpor, both intact mitochondria and succinate dehydrogenase (SDH) have higher apparent affinity for succinate, but SDH is inhibited by ca. 25%[2]. The inhibition of SDH is probably caused by oxaloacetate (OAA), a Krebs cycle intermediate, and the apparent affinity of SDH for OAA increases in torpor. Reversal of OAA inhibition (by preincubation with isocitrate) restores SDH activity, but it does not fully "rescue" state 3 respiration to euthermic levels[4]. Our recent phosphoproteomic analysis revealed seasonal (i.e. summer vs. winter) differences in the phosphorylation state of several mitochondrial proteins, but no differences within winter (i.e. torpid vs. aroused), when the rapid and reversible suppression of oxidative phosphorylation is most evident. Future experiments will examine potential inhibition of oxidative phosphorylation complexes by measuring their redox state in intact mitochondria using rapid-scanning optical spectrometry. We will also examine

changes in mitochondrial protein acetylation state using immunoblot analysis, and inhibition of substrate transport, especially by the dicarboxylate carrier which is responsible for succinate transport.

Translating drug-induced hibernation to therapeutic hypothermia

K.L. Drew, V.M. Combs and T.R. Jinka

Institute of Arctic Biology, University of Alaska Fairbanks, Fairbanks, AK, USA

Hibernation is a fully reversible condition characterized by hypometabolism and deep hypothermia. Core body temperature (Tb) in hibernating ground squirrels decreases to within 1 or 2°C of ambient temperature (Ta) and can fall to as low as -3°C (Barnes, 1989). In recent work, we showed that the arctic ground squirrel enters hibernation through activation of CNS adenosine A1 receptors (A1AR) (Jinka et al., 2011), in a manner consistent with the inhibition of thermogenesis. Similarly, A1AR agonists in nonhibernating species mediate a hypothermic response through effects on the CNS (Anderson et al., 1994).

Several aspects of the hibernation phenotype have therapeutic implications (Drew et al., 2001). Here we harness mechanisms hibernating animals use to cool during onset of torpor for therapeutic hypothermia (TH). TH is the only treatment known to improve prognosis for cardiac arrest patients (Hypothermia-after-Cardiac-Arrest-Study-Group, 2002). Thermoregulatory responses such as shivering, however, complicate cooling in comatose cardiac arrest patients and limit efficacy of TH in conscious stroke patients (Zgavc et al., 2011). Stimulating CNS A1AR to suppress thermogenesis mimics the process hibernating animals use to cool during onset of hibernation. Here we describe a strategy of targeted temperature management based on principles of CNS control of hibernation. All work on animals was approved by the UAF IACUC.

In these experiments the A1AR agonist ^{6}N-cyclohexyladenosine (CHA) was administered to rats (male, 69-75 days old; 250-350g, n=6) at a Ta of 16°C to lower body temperature. 8-(p-Sulfophenyl)theophylline (8-SPT), a nonselective adenosine receptor antagonist that does not cross the blood brain barrier was administered prior to CHA to mitigate direct effects of CHA on the heart. Asphyxial cardiac arrest was performed as before (Dave et al., 2006). Rats were anesthetized with 4% isoflurane and a 30:70 mixture of O_2 and N_2O followed by endotracheal intubation and mechanical ventilation. Vecuronium (1mg/kg) was injected iv and apnea induced by disconnecting the ventilator from the endotracheal tube to induce cardiac arrest. Adequacy of isoflurane anesthesia was assessed prior to onset of neuromuscular blockade and maintained at this level for less than 10 min before cardiac arrest induced a comatose state. Resuscitation was initiated after 8 min of apnea. Rats resuscitated within 120 sec were screened for additional inclusion criteria and randomly allocated to TH or normothermic control (NC) treatment groups. Subcutaneous body temperature was monitored using IPTT-300 transponders (Biomedic Data Systems, Inc., USA).

Treatments: The TH group was administered 8-SPT (25mg/kg,ip) 15min prior to CHA 1mg/kg,ip. This drug combination was administered 6 times at 4h intervals to rats held at a Ta of 16°C. The NC group was administered 8-SPT vehicle (saline) 15 min prior to CHA vehicle (0.1M phosphate buffer) in the same manner as 8-SPT/CHA and held in a neonatal incubator set to 29°C. Treatment commenced 70min after restoration of spontaneous circulation (ROSC) and continued for 24h. The final injection of CHA was administered at 20h and rats rewarmed at 24h by returning to the home room at a Ta of 20°C.

Histology: 7 days after ROSC rats were perfused as before (Dave et al., 2006) and hippocampal CA1 regions examined for histopathology.

Results: Mean ± SEM Tb was 33.5°C±0.07 and 33.5°C±0.14 in the NC and TH groups at onset of treatment. Tb in all 3 NC rats increased to 36.5-36.8 within 15 min of placement at 29°C and remained between 36.2 and 37.3°C until death. Only 1 rat in the NC group survived to 7 days. The remaining 2 rats died between 13-18h after ROSC. Tb in the 3 rats treated with TH decreased to 31.0 to 31.6°C within 3h of CHA injection and remained between 31.8 and 29.2°C for 24h before rewarming. Rats rewarmed within 5h after transfer to a Ta of 20°C, 4h after the last injection of CHA. Qualitative assessment of CA1 histopathology in TH treated rats indicated an absence of pathology; the CA1 in TH treated rats appeared similar to CA1 in naïve rats. Quantitative analysis by an observer unaware of treatment indicated that the number of healthy neurons in CA1 of TH treated rats was not statistically different from naïve rats, p=0.154, n=3-5.

Conclusion: Activation of CNS A1AR in animals exposed to a thermal gradient (Ta of 16°C) is a simple and effective means of inducing TH. Animals cooled in this manner survived cardiac arrest better than control treated animals and showed no evidence of histopathology in CA1 when compared to naïve rats. These results suggest that by mimicking mechanisms used by hibernating animals to cool it will be possible to administer therapeutic hypothermia in a highly effective, noninvasive and reversible manner.

Waking to drink: rates of evaporative water loss determine arousal frequency in hibernating bats

M. Ben-Hamo and B. Pinshow

Mitrani Department of Desert Ecology, Ben-Gurion University of the Negev, Midreshet Ben-Gurion, Israel

Hibernation is an adaptive strategy in bats that facilitates coping with low ambient temperatures (T_a) and scarce food during winter. The decline in metabolic rate (MR) and body temperature (T_b) of a bat during hibernation brings about a significant reduction in nutrients and water use, enhancing the probability of survival (Geiser and Koertner, 2010). However, hibernation is not a constant state of reduced T_b and MR, rather it comprises bouts of torpor interspersed with periods of arousal, when the animal returns to its normothermic T_b and MR (French, 1985). Although, bats arouse for only 5-10% of the time that they hibernate, arousals can account for over 85% of a hibernating bat's energy expenditure (Wang, 1978). Many different hypotheses attempting to explain periodic arousals have been proposed (Thomas and Geiser, 1997); all relate arousals to processes, such as metabolism and water loss, that vary in the same direction with T_b and T_a. Consequently, they give rise to the same prediction, namely that torpor bout length (TBL) is negatively correlated with T_a and T_b. This correlation alone cannot establish a causal link between arousal and the proposed processes, and, in addition, it introduces a difficulty in distinguishing between the hypotheses. We tested the "water balance" hypothesis, first proposed by Fisher and Manery (1967) that asserts that hibernating animals continuously lose water through evaporation while hibernating, and the ensuing dehydration initiates arousals, during which the animal rehydrates by drinking (Thomas and Geiser, 1997).

We tested our hypothesis in groups of a small bat, Kuhl's pipistrelle (*Pipistrellus kuhlii*), that were all maintained at constant T_a and constant absolute humidity. We assumed that at constant T_a, bats have similar T_bs and MRs, and that water vapor density at the skin surface is saturated at skin temperature. We manipulated the difference in water vapor density (e_w) between the skin surface (e_s) and the adjacent ambient air (e_a) by changing e_a, and measured water loss in Kuhl's pipistrelles in both dry and humid air, at constant T_a.

We found that TBL and TEWL were significantly related in hibernating Kuhl's pipistrelles, independent of MR and/or T_a, supporting the water balance hypothesis, while distinguishing it from other hypotheses that relate processes correlated with MR, T_a, or both. We also found that arousal frequency during hibernation was positively related with the amount of body mass (m_b) lost during this period, suggesting that bats with higher rates of TEWL that awoke more frequently lost more m_b and thus end hibernation with smaller fat reserves. These results demonstrate the importance of TEWL in survival of overwintering bats. Most, if not all, temperate zone bats in both suborders, the Yangochiroptera and Yinpterochiroptera, are hibernators (Altringham, 2011). Therefore, due to the similarities in the ecological and behavioral characteristics of these animals, the possibility exists that what we found in *P. kuhlii*, a vespertilionid bat, may occur in other hibernating bat species of different families.

SA464

Remodeling of cardiac excitation-contraction coupling in hibernation: comparison with heart failure

S. Wang

State Key Lab of Biomembrane and Membrane Biotechnology, Peking University College of Life Sciences, Beijing, China

Hibernating mammals survive winter season by periodically lowering their body temperature down to the freezing point. The hibernation regulation therefore means a great challenge to their cardiovascular systems. To elucidate the underlying adaptation, we compared the excitation-contraction (E-C) coupling in ventricular cardiomyocytes from hibernating (HGS) and awake (AGS) ground squirrels. Whole-cell voltage clamp showed that the current through L-type Ca2+ channels (LCC) was down-regulated in HGS compared with that in AGS. However, simultaneous recording of fluo-4 fluorescence revealed that the Ca2+ transient triggered by LCC current was not decreased. The gain of Ca2+-induce Ca2+ release (CICR) was thus enhanced remarkably in hibernation. To seek the molecular mechanisms, we investigated the intermolecular signaling between a single LCC and ryanodine receptors (RyRs). Loose-patch confocal imaging showed that the LCC-RyR coupling exhibited shortened latency and increased chance-of-hit in HGS. The enhancement of LCC-RyR signaling efficiency was not attributable to any difference in the Ca2+ contents in the sarcoplasmic reticulum (SR). Realtime PCR and western blot both revealed that the expression of junctophilin-2, a protein anchoring the RyR-residing SR to the LCC-residing T-tubules, was up-regulated in HGS. These data indicated hibernation comes with a regulation that enhances the efficiency of E-C coupling in heart cells. This molecular and functional remod-

eling is exactly opposite to that occurring in failing hearts, and thus provides an ideal research model for seeking new strategies against heart failure.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA465

Characterization and engineering of natural photoreceptors for optogenetic applications

G. Nagel

Univ. Wuerzburg, Wuerzburg, Germany

In order to study functioning of cells it is often helpful to disturb the cellular equilibrium and to analyze the consequences. Ideally this is achieved non-invasively and in a living organism. Light is an ideal medium for this purpose in translucent organisms but can also easily be applied via thin fibres in non-translucent animals. Light-sensitive proteins (photoreceptors) from one organism might render another one light-sensitive if expressed in specific cells. Photoreceptors from archaea, bacteria, and green algae were molecularly identified in recent years. We could show that some of them are ideal tools to manipulate animal cells by illumination. We showed that the Channelrhodopsins from the unicellular green alga C. reinhardtii are Light-gated cation channels which allow fast light-induced depolarization of the plasma membrane (1,2). Mutations led to a slower photocycle and therefore to Channelrhodopsins with higher light sensitivity. Neuronal expression of Channelrhodopsin-2 (ChR2) yields Light-induced action potentials and Light-manipulated behaviour in C. elegans (3) and other transgene animals. We demonstrated that the Light-activated chloride pump halorhodopsin (HR) from the archaeum Natronomonas pharaonis efficiently hyperpolarizes the plasma membrane and allows Light-induced silencing of neurons (4). These two antagonistic rhodopsins may even be expressed in the same cell and still specifically be light-activated with 460 nm for ChR2 and 580 nm for HR. Photoactivated Adenylyl Cyclases (PAC) from Euglena gracilis (5,6) or Beggiatoa spec. (7) are flavoproteins which quickly elevate cytoplasmic cyclic AMP by illumination with blue light in cultured cells and living animals or plants. Recently we identified and characterized a further bacterial PAC with high cAMP production.

Towards the Dynamictome

A. Vaziri

Research Institute of Molecular Pathology (IMP) & Center for Molecular Biology, University of Vienna, Vienna, Austria

Knowledge on structural connectivity in neuronal circuits is necessary for understanding information representation and processing in local circuits. However, as some examples of well-characterized neuronal architectures illustrate, structural connectivity alone it is not sufficient to predict how input stimuli are mapped onto activity patterns of neuronal populations and how the collective dynamics of all neurons in the network leads to behavior. Addressing this challenge has been hampered by lack of appropriate tools and methods that allow parallel and spatiotemporally specific application of excitation patterns onto neuronal populations while capturing the dynamic activity of the entire network at high spatial and temporal resolution. I will discuss how the combination of new optical excitation techniques, optogenetics and imaging are providing new opportunities to address this challenge and move towards a dynamic map of neuronal circuits, the "Dynamictome".

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

SA467

The use of optogenetics to probe the role of spontaneous rhythmic activity and cyclic AMP transients during in-vivo spinal motor circuit development

L.T. Landmesser, K.K. Kastanenka and Y. Maeno-Hikichi

Neurosciences, Case Western Reserve University, Cleveland, OH, USA

Developing spinal cords of birds and mammals exhibit rhythmic waves of spontaneous electrical activity during initial motor axon outgrowth. In chick embryos electroporated channelrhodopsin-2 can be activated in-ovo to chronically drive waves at different frequencies, avoiding the complication of altering frequency by drugs that affect different neurotrans-

mitter systems, as carried out in previous experiments. Motor axon pathfinding was found to be highly sensitive to the frequency of such waves, as modest decreases in frequency selectively affected the binary dorsal-ventral pathfinding decision and the expression of molecules involved in this guidance choice, while modest increases selectively disrupted the subsequent motoneuron pool-specific pathfinding choice. The ability to precisely control in-vivo wave frequency non-invasively by light should facilitate the elucidation of the intracellular signaling pathways underlying these divergent pathfinding choices and the extent to which the frequency versus the pattern of the waves is important. This approach should also aid in the discovery of other activity dependent aspects of spinal cord development. In the retina and spinal cord waves trigger Ca2+ transients which in turn generate transients of cAMP. To explore the role of cAMP transients we have used a light activated bacterial adenylyl cyclase to cause cAMP transients in cultured motoneurons and in intact spinal cords in-ovo. Such transients affected growth cone behavior of cultured motoneurons and generated spontaneous waves in isolated spinal cords and in intact embryos in-ovo. While additional experiments are needed these optogenetic tools should prove valuable in further characterizing the roles of Ca2+ and cAMP transients and their possible interactions in motor axon pathfinding and circuit development.

Optogenetical approach to reveal the regulatory mechanism of instinctive behaviors by the hypothalamic neurons

A. Yamanaka and T. Tsunematsu

Research Institute of Environmental Medicine, Nagoya University, Nagoya, Japan

IInstinctive behaviors, such as sleep/wakefulness, feeding and sexual behaviors are regulated by the hypothalamic neurons. Recent research revealed that the hypothalamic neurons containing neuropeptides are implicated in the regulation of these instinctive behaviors. It is essential to study neural regulatory mechanisms of these instinctive behaviors using a whole animal since these instinctive behaviors are exhibited only therein. Optogenetics enable control of the activity of specific type of neurons in the whole body animal using light. We apply optogenetics to Orexin/hypocretin-producing neurons (orexin neurons). Orexin neurons are located in the hypothalamus but project their efferents throughout the brain. Intriguingly, mice lacking the prepro-orexin gene showed behavioral characteristics similar to human sleep disorder "Narcolepsy", that is a fragmentation of sleep/wakefulness and sudden muscle weakness. Human clinical studies also showed that orexin neurons are specifically degenerated in the narcoleptic patient's brain. These results suggest that the orexin neurons play a critical role in the regulation of sleep/wakefulness. Previous studies using electrophysiological in vitro techniques have identified potential neuronal pathways or networks connecting orexin neurons with other neurons which are known to be involved in sleep/ wakefulness regulation. To apply optogenetics to orexin neurons, we generated transgenic mice in which specifically express halorhodopsin or Archaerhodopsin-3, a light driven neural silencer. In these mice brain more than 90% of orexin neurons express halorhodopsin or Archaerhodopsin-3. Acute inhibition of orexin neurons (~1hr) using optogenetics induced fragmentation of sleep/wakefulness in the early dark period (Figure), but not cataplexy-like behavioral arrest, which is characteristic symptom in narcoleptic patient. This result might suggest that chronic inhibition of orexin neurons might be caused to trigger cataplexy-like behavioral arrest. Our current research involves applying optogenetics in the hypothalamic peptide-containing neurons to reveal regulatory mechanisms of these instinctive behaviors.

Optogenetic delivery of touch sense into peripheral and central nervous systems

H. Yawo[1,2], T. Honjoh[1,2], Z. Ji[1,2], Y. Yokoyama[1,2], A. Sumiyoshi[3], S. Ito[1,2], T. Ishizuka[1,2], R. Kawashima[3], H. Ohta[4] and Y. Fukazawa[5]

[1]Developmental Biology and Neuroscience, Tohoku University Graduate School of Life Sciences, Sendai, Japan, [2]JST, CREST, Sendai, Japan, [3]Institute of Development, Aging and Cancer, Tohoku University, Sendai, Japan, [4]Department of Physiology, National Defense Medical College, Tokorozawa, Japan and [5]Department of Anatomy and Molecular Cell Biology, Nagoya University Graduate School of Medicine, Nagoya, Japan

All knowledge about the world is perceived through our sensory systems which consist of peripheral sensory organs, sensory nerves and central nervous system (CNS). In principle a sensation is classified according to its modality, a kind of energy inducing physiological transduction in a specific group of sensory organs. For example, in the somatosensory systems, each mode of touch-pressure, temperature or pain is sensed by independent sensory endings of primary afferent neurons and conducted to the specific cortical locus as nerve impulses, but integrated thereafter as a whole. Although it has been anticipated that the peripheral sensory nerve endings would become photosensitive with the ectopic expression of photoreceptive molecules, it has never been proved with the mammalian systems. Could the animal sense light on its skin if the peripheral sensory nerve endings are photosensitive? In one of trans-

genic rat lines which express channelrhodopsin-2 (ChR2), one of algal photoreceptive molecules (1, 2), the light is sensed by skin through the touch-pressure sensitive nerve endings. We provided evidences for the first time that the sensory modality of the somatosensory system can be modified so as to be also reactive to light even in the rat.

We have previously generated several lines of transgenic rats which express ChR2 under regulation of Thy1.2 promoter (3). The transgene expression was variable from line to line, being dependent on the integration sites in chromosomes and/or the number of inserted copies (4). In one of these transgenic rat lines, W-TChR2V4, ChR2 was specifically expressed in a subpopulation of mechanoreceptive neurons in the dorsal root ganglion (DRG) but not in the small-sized neurons which are involved in nociception. Furthermore, ChR2 is also expressed in their peripheral nerve endings such as those innervating Merkel corpuscles and Meissner corpuscles, which are involved in the touch sense. Indeed, this transgenic rat showed a sensory-evoked behavior in response to blue flash light on their plantar skin as if it were touched by something. However, it ignores red light that is not sensed by ChR2. It is thus concluded that the rat has acquired an unusual sensory modality that it senses light at skin (5).

We also identified the expression of ChR2 in the peripheral endings of trigeminal mechanoreceptive neurons which innervate whisker follicles. Is a whisker-related sensory perception induced by the photostimulation of their follicles? To test this, the barrel cortex responses were examined using electrophysiological recordings and functional magnetic resonance imaging (fMRI). Under anesthesia with urethane, the whiskers were trimmed and connected with optic fibers of which other endings were connected to LEDs. Pulsative irradiation of blue LED light was used as a test and that of red LED light as control.

We found that the blue light irradiation of whisker follicles evoked enhanced unit activities as well as a local field potential in the barrel field of contralateral somatosensory cortex whereas the red light did not. The blue light irradiation also induced blood oxygenation level-dependent (BOLD) and cerebral blood volume (CBV) responses in the barrel field of contralateral somatosensory cortex. It is suggested that the optogenetic whisker stimulation could activate the whisker-barrel cortical pathway of mechanoreceptive signaling.

The light-evoked somatosensory would facilitate the study how the complex tactile perception such as form, movement, size and texture is generated. The various and reproducible patterned tactile stimulations could be easily made by the patterned illuminations on the whisker pad without using any mechanical instruments. Since our rat system does not express ChR2 in the nociceptive pathway, it enables one to do in vivo experiments without ethical problems. It would particularly beneficial for the researches using fMRI because the illumination system would not influence the magnetic fields. The light-evoked somatosensory perception should facilitate study of how the complex tactile sense emerges in the brain.

Xanthohumol reduces transcription of pro-inflammatory markers TNF-α, IL-1β, NFκB2, and HO1 in the lung of senescence-accelerated prone mice (SAMP8)

S. Paredes[1], A. Carrasco[2], L. Rancan[2], R. Kireev[1], E. Vara[2] and J. F. Tresguerres[1]

[1]Department of Physiology, Complutense University of Madrid, Madrid, Spain and [2]Department of Biochemistry and Molecular Biology III, Complutense University of Madrid, Madrid, Spain

Lungs are highly vascularised organs directly exposed to atmospheric oxygen. Consequently, they are an important source of reactive species that seem to be involved in local defense against pathogens. With age, increased production of free radicals, together with a reduced antioxidant defense activity, may surpass the antioxidative capability of lungs, leading to lung damage and increasing susceptibility to other pathologies. Xanthohumol, the major prenylated chalcone found in hops, has been shown to present anti-inflammatory and antioxidant properties in several organs, including liver, brain, and at the level of the reproductive system. Its effect on the aging lung has yet to be elucidated. For this reason, the aim of the present study was to evaluate the possible anti-inflammatory role of xanthohumol on a model of male senescence-accelerated prone mice (SAMP8). Young and old animals, aged 2 and 10 months respectively, were maintained under a 12:12 h light-dark cycle in an environmentally-controlled room and fed ad libitum. They were divided into 4 experimental groups: Young non-treated, old non-treated, old treated with 1 mg/kg/day xanthohumol, and old treated with 5 mg/kg/day xanthohumol. Young and old non-treated male senescence-accelerated resistant mice (SAMR1) were used as controls. Xanthohumol was dissolved in ethanol and added to the drinking water. Only ethanol was administered to the water of non-treated animals. After 30 days of treatment, animals were sacrificed and lungs were collected and immediately frozen in liquid nitrogen. mRNA expression of tumor necrosis factor-alpha (TNF-α), interleukin-1 beta (IL-1β), nuclear factor NF-kappa-B p100 subunit (NFκB2), and heme oxygenase 1 (HO1) was measured by means of RT-PCR using the SYBR Green PCR Master Mix (Applied Biosystems, Warrington, UK) and 300 nM concentrations of specific primers. For the normalization of cDNA loading in the PCR reaction, the amplification of 18S rRNA for every sample was used. Relative changes in gene expression were calculated using the 2-ddCt method. Mean values were analyzed by ANOVA. Compared to the young animals, old non-treated SAMP8 mice presented significantly elevated ($P<0.05$) mRNA levels of TNF-α, IL-1β, NFκB2, and HO1. SAMR1 mice showed significantly decreased ($P<0.05$) mRNA levels of these pro-inflammatory markers in comparison with the old non-treated SAMP8 group. Treatment with xanthohumol was able to decrease significantly ($P<0.05$) the age-induced elevation at any of the doses administered. Supplementing the diet with foodstuffs containing xanthohumol may be used as a potential tool for counteracting inflammation and oxidative stress in the aging lung.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Melatonin decreases the expression of inflammation and apoptosis markers in the lung of a senescence-accelerated mice model

A. Puig[1], L. Rancan[1], S. Paredes[2], G. Yoldi[2], R. Kireev[2], E. Vara[1] and J. F. Tresguerres[2]

[1]Department of Biochemistry and Molecular Biology III, Complutense University of Madrid, Madrid, Spain and [2]Department of Physiology, Complutense University of Madrid, Madrid, Spain

Aging is associated with an increase in oxidative stress and inflammation. Aging lung is particularly affected to this damage since alveolar epithelial cells are continuously exposed to environmental oxidants and antioxidant machinery seems to be weakened with age. Melatonin is a potent free radical scavenger and broad spectrum antioxidant that has been shown to counteract inflammation and apoptosis in healthy cells. Its effect on aging lung is, however, not yet fully understood. Thus, the aim of the present study was to investigate the effect of the exogenous administration of melatonin on the mRNA expression of inflammation markers tumor necrosis factor-alpha (TNF-α), interleukin-1 beta (IL-1β), nuclear factor NF-kappa-B p100 subunit (NFκB2), heme oxygenase 1 (HO1) and apoptosis parameters Bcl-2-associated death promoter (BAD) and apoptosis inducing factor (AIF) in male senescence-accelerated prone mice (SAMP8). Young and old animals, aged 2 and 10 months respectively, were maintained under a 12:12 h light-dark cycle in an environmentally-controlled room and fed ad libitum. They were divided into 4 experimental groups: Young non-treated, old non-treated, old treated with 1 mg/kg/day melatonin, and old treated with 10 mg/kg/day melatonin. Young and old non-treated male senescence-accelerated resistant mice (SAMR1) were used as controls. Melatonin was dissolved in ethanol and added to the drinking water. Only ethanol was administered to the water of non-treated animals. After 30 days of treatment, animals were sacrificed and lungs were collected and immediately frozen in liquid nitrogen. mRNA expression was measured by means of RT-PCR using the SYBR Green PCR Master Mix (Applied Biosystems, Warrington, UK) and 300 nM concentrations of specific primers. For the normalization of cDNA loading in the PCR reaction, the amplification of 18S rRNA for every sample was used. Relative changes in gene expression were calculated using the 2-ddCt method. Mean values were analyzed by ANOVA. Old non-treated SAMP8 animals showed significantly increased ($P<0.05$) levels of TNF-α, IL-1β, NFκB2, and HO1 with respect to the values obtained in the young group. SAMR1 mice showed significantly decreased ($P<0.05$) mRNA levels of these pro-inflammatory markers in comparison with the old non-treated SAMP8 group. Melatonin treatment with either dose tested was able to reverse significantly ($P<0.05$) the aging-derived augmentation of these inflammatory markers. In addition, BAD and AIF expression rose with aging, the effect being significantly counteracted ($P<0.05$) with melatonin administration. Melatonin treatment may modulate the inflammatory and apoptosis status of the aging lung, exerting a protective effect on age-induced damage.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Ageing is associated with changes in structure and ion channel expression within the atrioventricular conduction axis

Y. Saeed, Z. Borbas, I. Temple, A. Atkinson, J. Yanni, M. Boyett, C. Garratt and H. Dobrzynski

Cardiovascular Research Group, University of Manchester, Manchester, UK

Introduction:The inferior nodal extension (INE), compact atrioventricular (AV) node and penetrating/His bundle (PB) form the AV conduction axis and are responsible for delay and propagation of the action potential from the atria to the ventricles. With ageing, dysfunction in these tissues results in prolongation of the PR interval and first, second and third degree AV block. The only treatment is implantation of permanent pacemakers, which are known to be associated with various complications. Previous studies have described age-related structural and functional changes in the AV conduction axis, but detailed examination of morphological changes (fibrosis and hypertrophy) as well as changes in ion channel expression with ageing have not been investigated.
Methods: We have compared the regions of the AV conduction axis (INE, compact AV node, CN, proximal PB, PPB and distal PB, His bundle) from 3 (n=9) and 24 (n=8) months old male rats (humanely killed in accordance with UK Animals Scientific Procedures Act 1986). From the survival curve, 3 months old rats correspond to 20 years old humans, whereas 24 months old rats correspond to ~70 years old humans. Morphological characteristics of these tissues were studied using serial cryosections and Masson's trichrome (MT) and picrosirius red (PR) histological stains and light and polarised microscopy. The expression of the ion channel HCN4 (responsible for pacemaking) and the gap junction channels Cx43 and Cx40 (responsible for electrical coupling between cardiac cells) was studied using immunofluorescence and confocal microscopy. Qualitative signal intensity of these channels was measured using Volocity software. Statistical analysis was performed using independent t test with SPSS version 20.1.
Results: At the structural level, we observed significant changes with ageing. MT staining showed that the cells of INE, CN, PPB and His bundle are more loosely packed and irregularly arranged in older animals. Age-dependent cellular hypertrophy was confirmed by a statistically significant increase in cell size across all regions of the AV junction. With ageing, total collagen content estimation showed a statistically significant increase in thin (but not in thick) collagen fibres in the CN, PPB and His bundle. Immunohistochemistry revealed a decrease in Cx43 expression in the INE (P=0.003), PPB (P=0.005), His bundle (P=0.02), but an increase in Cx40 expression in the INE (P=0.01) and CN (P=0.005) with ageing. There was also trend to downregulation of HCN4 expression especially in the His bundle (P=0.051).
Conclusion: Ageing is associated with structural changes of the AV junction tissues, which include fibrosis, hypertrophy and changes in Cx43 and Cx40 and possibly HCN4 expression. Our current findings may explain the prolongation of the PR interval with ageing observed in our previous study.1

PCA005

Ageing has heterogeneous effects within the left ventricle and between genders on mRNA expression for key calcium-regulatory proteins

L.T. Cheah, K. Rostron, J. Wilkinson and M.K. Lancaster

School of Biomedical Sciences, University of Leeds, Leeds, UK

Progressive ageing associates with an increasing incidence of cardiac dysfunction and arrhythmias. Such problems are likely to be contributed to by changes in cardiac intracellular calcium regulation but findings are often inconsistent possibly due to a mix of sample types, ages, species and genders studied.
This study used quantitative PCR (qPCR) to assess expression of mRNA for proteins involved in cellular calcium regulation across the wall of the left ventricle (LV) in both genders at three age points: young (6 months), adult (12 months) and old (24 months). C57Bl6 mice (n=6 for each gender at each age) were euthanised by cervical dislocation and samples from the sub-endocardial (endo) and sub-epicardial (epi) LV free wall dissected. Following mRNA isolation, samples were subjected to qPCR with results normalised to GAPDH mRNA abundance. Data were assessed by Pearson correlation or ANOVA.
The effects of ageing on key transcripts are summarised in Table 1. The combined data showed significant negative correlations between age and mRNA expression for the L-type Ca^{2+} channel, D-type Ca^{2+} channel, the cacna1h isoform of the T-type Ca^{2+} channel, ryanodine receptors (RYR), phospholamban (PLB) and calcium-calmodulin dependent protein kinase 2 (CAMK2D). Analysing individual genders these age-associated declines were common to males and females for PLB but all other correlations were significant in males only, aside for that of the D-type Ca^{2+} channel decline which correlated with age only in females.
No regional heterogeneity of changes was observed in females. In contrast in males the cacna1h isoform of the T-type Ca^{2+} channel, and CAMK2D fell significantly with age in endo only, whilst a rise in calsequestrin mRNA was unique to this region. RYR mRNA fell in both endo and epi whilst PLB mRNA fell significantly only in epi. SERCA2a mRNA remained unchanged, as did that for the cacna1g isoform of the T-type Ca^{2+} channel, sarcolemmal Ca^{2+} pumps (PMCA1 and 4), sodium-calcium exchanger and sodium-potassium pump α1 isoform.
In conclusion, ageing has heterogeneous effects on mRNA transcript abundance for key regulatory proteins dependent on gender and ventricular region. The majority of changes were observed in the male heart alone where increasing heterogeneity of expression across the LV wall may predispose to dysfunction and arrhythmias.

Table 1: Percentage Change in mRNA Abundance with Ageing

	L-type Ca^{2+} channel	T-type Ca^{2+} channel (Cacna1h)	T-type Ca^{2+} channel (Cacna1g)	RYR	PLB	SERCA2a	CAMK2D
Combined	-17.7±14.5*	-45.5±26.0*	+4.7±25.2	-28.5±12.5*	-26.4±4.7*	-1.8±8.3	-17.5±8.2*
Male	-22.4±13.2	-50.4±22.5*	+1.4±9.9	-42.6±10.0*	-30.9±4.2*	+7.5±7.6	-18.7±13.6*
Female	-12.8±16.1	-34.8±15.4	+8.2±14.3	-11.1±8.8	-21.3±5.7*	-7.2±9.5	-16.1±11.1
Male-endo	-19.6±11.9	-56.1±17.1^	+62.1±18.4	-37.0±13.4^	-12.1±39.5	+18.3±4.7	-23.5±4.9^

The effects of velocity and temperature on swimming performance in rainbow trout (Oncorhynchus mykiss)

A. Keen, E. John, H. Shiels and R. Nudds

Faculty of Life Sciences, University of Manchester, Manchester, UK

The reproductive success of many salmonid species relies on successful migration to natal spawning grounds. Energy efficient locomotion, dictated by cost of transport (COT), may be an important selection pressure for completion of migratory routes. In addition, climate change poses further difficulties for migration due to elevated temperatures and varying water velocities. To explore how temperature affects efficiency of locomotion, rainbow trout (Oncorhynchus mykiss) were subjected to a modified critical swimming speed (UCrit) test, while oxygen consumption (MO2) and swimming form were recorded, at acclimation (11°C) and high (20°C) temperature. Calculation of strouhal numbers (St) enabled gait change to be assessed in terms of swimming efficiency and performance. Increasing temperature from 11-20°C gave a large increase in oxygen consumption (Q10 = 1.67). Incremental increase in swimming speed (from 1 Bl s-1 to UCrit) resulted in further increases in oxygen consumption (349.942 ± 53.02 and 423.185 ± 51.5 1mg O2 kg-1 h-1 for controls and high temperature, respectively). However, the rate of MO2 increase with increasing water velocity was not different between the two temperature groups, or at different gaits. As previously shown, tail beat frequency and amplitude increased to accommodate greater speed, up to the onset of burst and glide gait, but at high speeds tail beat amplitude alone was modulated. Rainbow trout swum within the strouhal number range for optimum propulsive efficiency (0.2 < St < 0.4), as seen in numerous animals. Increased velocity and gait change did not affect strouhal numbers at low temperature. However, at high temperature strouhal number increased with speed, due to an augmented tail beat frequency at high temperature. This result suggests a higher muscle twitch rate at high temperature, in agreement with previous muscle physiology data.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA008

Anemia in medical students and its relationship with heart rate variability

K. Agrawal[1], B.H. Paudel[1], R. Khadka[1], N. Upadhyay[1], S.K. Dev[1] and S.N. Majhi[1,2]

[1]Physiology, BPKIHS, Dharan, Nepal, Dharan, Nepal and [2]Biochemistry, B.P. Koirala Institute of Health Sciences, Dharan, Nepal

Anemia is prevalent in pregnant ladies. It is also common in college girls and other age groups of female. Anemia has been found to be associated with low heart rate variability (HRV) indicating increased cardiac risk. Medical students are under stress, which may affect both the hemoglobin level and HRV. Thus, we aimed to assess the hemoglobin, iron status, and HRV. A cross-sectional comparative study was conducted on 40 unmarried female medical students of age 18-30 years. They were divided into three groups based on hemoglobin (Hb) level following WHO guidelines: normal Hb group (Hb≥12g/dl), mild anemia (Hb<11.9-10.0g/dl) and moderate anemia (Hb 9.9-7.0g/dl). Their mean corpuscular volume, RBC counts and ferritin levels were measured. Short-term heart rate variability and cardio-respiratory variables were recorded in all subjects after 15 min of supine rest and compared among the groups. The relationship between HRV and blood parameters was studied using Spearman's Rank correlation. Kruskal Wallis followed by multiple comparisons was applied to compare the variables of blood and HRV among the groups. According to Hb level, 17.5% students were moderately anemic, 50% were mild anemic and 32.5% were with normal Hb level. They were comparable in terms of their age, BMI, diastolic blood pressure and heart rate. However, systolic blood pressure [92(90.0-110.0) mmHg vs. 110(108.5-112) mmHg, p=0.022] and respiratory rate [18(16-18) per minute vs. 20(19-22) per minute p= 0.001] were lower in moderate anemic group compared to normal group. Also systolic blood pressure [92(90.0-110.0) mmHg vs. 110(102-110) mmHg, p= 0.042] was lower in moderate anemic group than mild anemic group. The Hb level, RBC count, MCV, and ferritin levels { [9.2 (9.0-9.8) g/dl vs. 11.0 (10.17-11.45) g/dl vs. 12.4(12.0-12.65) g/dl, p= 0.001], [3.7(3.5-3.7) per mm3 vs. 4.0(3.9-4.1) per mm3 vs. 4.2(4.11-4.36) per mm3, p= 0.001], [77.94(77.29-82.97) fl vs. 85(78.76-88.7) fl vs. 90.06(86.33-92.54) fl, p= 0.01] and [7.9(6.5-19.4) ng/ml vs. 18.85(15.85-38.0) ng/ml vs. 28.9(17.3-44.7) ng/ml p=0.01]} respectively were lower in moderate anemic group than mild anemic and normal groups. However, there were no significant differences in HRV parameters among the groups, and no significant correlations were obtained between HRV and blood parameters. Moderately anemic female medical students had lower systolic BP and respiratory rate compared to mildly anemic female medical students. However, there were no significant differences in HRV parameters among the groups. It indicates mild and moderate anemia may not have effect on cardiac autonomic modulation in this female age group.

All the students, junior residents, computer staff and all who helped me directly or indirectly.

PCA009

Stimulation of M2-cholinoreceptors increases the outward current of sodium-calcium exchanger in fish atrial myocytes

D.V. Abramochkin[1,2], S.V. Tapilina[1] and M. Vornanen[3]

[1]Department of Human and Animal Physiology, Moscow State University, Moscow, Russian Federation, [2]Department of Fundamental and Applied Physiology, Russian National Research Medical University, Moscow, Russian Federation and [3]Department of Biology, University of Eastern Finland, Joensuu, Finland

Sodium-calcium exchanger (NCX) plays crucial role in regulation of cardiac calcium homeostasis and provides a key ionic current (I_{NCX}) involved into pacemaker activity of sinoatrial cardiomyocytes. However, modulation of I_{NCX} by autonomic neurotransmitters, which contribute to regulation of cardiac performance, still remains questionable. The present study provides the first evidence for direct modulation of I_{NCX} via muscarinic receptors. In atrial cardiomyocytes of crucian carp (*Carassius carassius L.*) and rainbow trout (*Oncorhynchus mykiss W.*) muscarinic agonist carbacholine (Cch, 10^{-6}-10^{-4}M) produced a strong increase of the outward I_{NCX} without any

changes in the inward I_{NCX}. A selective blocker of I_{NCX}, KB-R7943 (10^{-5} M), abolished the basal I_{NCX} (both inward and outward current), which was registered in the absence of Cch, as well as the Cch-induced outward I_{NCX}. In ventricular myocytes from both studied species even the high concentration of Cch (10^{-4} M) was completely ineffective due to the putative absence of muscarinic receptors. On the contrary, in the atrial cells muscarinic antagonist atropine (10^{-6} M), which blocks M-receptors without any subtype selectivity, completely eliminated the response of outward I_{NCX} to Cch, but did not affect the basal I_{NCX}. A selective antagonist of M2 cholinoreceptors, AF-DX 116 (2×10^{-7}M) and a M3 antagonist, 4-DAMP (10^{-9} M), decreased Cch-induced current by 84.4% and 16.6% respectively. Pertussis toxin, which irreversibly inhibits G_i-protein coupled to M2 receptors, reduced the Cch-induced I_{NCX} by 95%, when applied into the pipette solution. The present results indicate a vectorial cholinergic stimulation of I_{NCX} in fish atrial myocytes, predominantly mediated by M2 cholinoreceptors. We conclude that the selective stimulation of the outward component of I_{NCX} by M2 cholinoceptors represents a new molecular target for the cardiac parasympathetic innervations, which is present at least in fish myocardium.

Oral contraceptive-induced impaired glucose tolerance is associated with elevated plasma uric acid, triglyceride/high-density lipoprotein-cholesterol ratio but not with high C-reactive protein levels in female rats

L.A. Olatunji[1], S.A. Biliaminu[2], A.A. Safiriyu[1], O.A. Adeyanju[1], T.M. Abiodun[1] and A.O. Soladoye[1]

[1]Physiology, University of Ilorin, Ilorin, Kwara, Nigeria and [2]Chemical Pathology & Immunology, University of Ilorin, Ilorin, Kwara, Nigeria

Women are exposed to estrogen and/or progestogen through several means such as hormonal contraceptives and hormone replacement therapies. The cardiometabolic effects of using oral contraceptive (OC) in particular are still inconclusive (1). High C-reactive protein (C-RP), uric acid (UA) as well as triglycerides (TG)/high-density lipoprotein cholesterol (HDL-C) ratio are now widely accepted as salient atherosclerotic risk indicators, independently predicting future cardiovascular events (2-4). The present study therefore sought to determine the effects of combined OC steroids on C-RP, UA and TG/HDL-C ratio in a female rat model with impaired glucose tolerance. Twelve female Wistar rats weighing between 120 and 180g were randomly allotted to OC-treated (n=6) and vehicle-treated (n=6) groups. OC-treated rats received a combination of OC steroids (15.0 μg norgestrel and 1.5 μg ethinyl estradiol/rat; NEE, p.o.) while vehicle-treated rats were given distilled water (0.3ml/rat, p.o.) daily for 6 weeks. Rats had unrestricted access to food and water. An oral glucose tolerance test was performed after 12-hour overnight fast, and glucose tolerance was expressed as a function of the area under the tolerance curve (AUC). Values are means ± S.E.M., compared by independent t-test. When compared with the vehicle-treated rats, OC treatment led to significant decreases in glucose tolerance (AUC: 288.8±12.5 vs. 398.5.4±10.2mg/dl, $p<0.05$), circulating 17β-oestradiol (13.1±0.2 vs. 4.8±0.8pg/ml, $p<0.05$) and testosterone (0.38±0.02 vs. 0.11±0.03ng/ml $p<0.05$). On the other hand, there were significant increases in plasma UA (181.6±11.2 vs. 483.0±14.9μmol/L, $p<0.05$), TG (89.2±7.3 vs. 156.1±11.2mg/dl, $p<0.05$), TG/HDL-C ratio (1.8±0.2 vs. 3.2±0.1, $p<0.05$) with OC treatment. However, fasting blood glucose, plasma total cholesterol (TC), low-density lipoprotein-cholesterol (LDL-C), HDL-C, TC/HDL-C ratio, C-RP, total protein and albumin levels were not significantly affected by OC treatment. These results demonstrate that OC-induced impaired glucose tolerance is associated with high plasma UA and TG/HDL-C ratio, but not with increased plasma C-RP level. The findings imply that dyslipidemia associated with OC-induced impaired glucose tolerance may promote atherosclerotic complications, and that plasma level of UA but not that of C-RP may be an important factor to be monitored during OC use.

PCA011

The effects of blood components modulation on load-dependent cardiac function during an acute hemodilution

S. Chatpun[1] and P. Cabrales[2]

[1]Institute of Biomedical Engineering, Prince of Songkla University, Hatyai, Songkhla, Thailand and [2]Bioengineering Department, University of California, San Diego, La Jolla, CA, USA

Modulation of blood components, both red blood cells and plasma, particularly affects on circulatory system. This study investigated the load-dependent cardiac function and systemic changes after normovolemic hemodilution with four different transfusion fluids in anesthetized Golden Syrian hamsters. The investigation was performed in anesthetized 60–70 g male Golden Syrian hamsters. Animal handling and care followed the US National Institute of Health Guide for Care and Use of Laboratory Animals. Twelve hamsters were randomly divided into 4 groups (n=3 for each group). Anesthesia was induced by intraperitoneal injection of sodium pentobarbital (50 mg/kg) and core body temperature was maintained using a heating pad. Animal surgical preparation included: (i) left jugular vein for transfusion fluid injection, (ii) right common carotid artery for a pressure-volume conductance catheterization, (iii) left femoral artery for blood withdrawal, and (iv) tracheotomy with polyethylene-90 tube to facilitate spontaneous breathing. Normovolemic hemodilution was performed by the exchange of 40% of the animal's blood volume with transfusion fluid. Four different transfusion fluids included 3-week stored blood, dextran 70 kDa (viscosity 3.0 cP), low viscosity plasma volume expander (LVPE; 2% dextran 2000 kDa, viscosity

2.2 cP), and high viscosity plasma volume expander (HVPE; 6% dextran 2000 kDa, viscosity 6.4 cP). Left ventricular cardiac systolic function was quantitatively assessed with a pressure-volume conductance catheter. Values are means ± S.D., compared by ANOVA. Plasma viscosity after hemodiluted with HVPE was 2.12±0.10 CP after hemodilution while other groups were 1.01±0.10 (stored blood), 1.27±0.03 (dextran 70 kDa) and 1.21±0.05 cP (LVPE). Cardiac output at the end of experiment increased from baseline in the group hemodiluted with HVPE (10.35±2.38 ml/min at baseline vs 13.10±4.02 ml/min at the end of experiment) and dextran 70 kDa (10.685±2.62 ml/min at baseline vs 12.49±1.64 ml/min at the end of experiment). On the other hand, cardiac output in the group hemodiluted with LVPE was less than baseline (13.11±0.49 ml/min at baseline vs 10.96±0.91 ml/min at the end of experiment) that was similar to the group exchanged with stored (8.40±3.49 ml/min at baseline vs 6.76±2.85 ml/min at the end of experiment). Stroke work relative to baseline in the group hemodiluted with HVPE significantly increased compared to those in the group hemodiluted with LVPE (HVPE: 1.23±0.14 vs. LVPE: 0.81±0.15, $p<0.05$). These data suggest that modulation of plasma expander viscosity affects load dependent cardiac function. Stored blood reduces load dependent cardiac function when compared to baseline condition.

The authors thank Cynthia Walser for the surgical preparation of the animals.

PCA012

Effects of class III anti-arrhythmic agents with hERG channel block and facilitation on cardiac action potential: a simulation study

K. Furutani, K. Tsumoto, I. Chen and Y. Kurachi

Department of Pharmacology, Osaka University Graduate School of Medicine, Suita, Osaka, Japan

Potassium channels encoded by human ether-a-go-go-related gene (hERG) underlie the rapidly activating component of the delayed rectifying potassium current (IKr) in heart and play an important role in terminating the cardiac action potential (AP) (Sanguinetti & Tristani-Firouzi, 2006). hERG channel has been shown to be the target of class III anti-arrhythmic agents. It has also become clear that hERG channel is blocked by compounds with high pro-arrhythmic risk. The unintended block of hERG channel causes an acquired form of QT interval prolongation, worsens transmural dispersion of repolarization and forms the substrate for generation of life-threatening cardiac arrhythmias, including torsades de pointes. Recently, we have experimentally demonstrated a dual effect of some anti-arrhythmic agents, such as nifekalant, on hERG channel (Hosaka et al., 2007; Furutani et al., 2011). Besides blocking hERG channel, these compounds can facilitate its activation. To assess the clinical relevance of hERG channel modulations by compounds, we conducted simulations of cardiac AP in a modified Luo-Rudy model with hERG channel block and facilitation, using our experimental data of nifekalant. Then, we found that the hERG channel block prolonged action potential duration (APD) in the block conditions both with and without facilitation. In addition, the refractory period in both conditions equally increased from control condition so that the ectopic cell excitation is suppressed, suggesting that even if hERG channel blocker has facilitation effect, anti-arrhythmic efficacy of the drug is equivalent to that of pure blocker. As in our simulation, we could observe an early afterdepolarization (EAD) when both IKr and the slowly activating component of the delayed rectifying potassium current (IKs) were blocked. Importantly, facilitation mechanism prevents hazardous prolongation of APD and the induction of EAD by accelerating the repolarization rate via an increase in IKr during prolonged phase 3. Therefore, anti-arrhythmic agents that has both block and facilitation effects on hERG channel may have a lower risk for inducing EADs and triggered activity and thus be more suitable for the treatment of arrhythmias than pure hERG blocker.

Ischemia-induced subcellular remodeling of sodium channels as a mechanism of ventricular proarrhythmia by class-I antiarrhythmic drug

K. Tsumoto[1], T. Ashihara[2], R. Haraguchi[3], K. Nakazawa[3] and Y. Kurachi[1]

[1]Osaka University, Suita, Japan, [2]Shiga University of Medical Science, Otsu, Japan and [3]National Cerebral and Cardiovascular Center Research Institute, Suita, Japan

Background: Na channel blockade has a long history used for the treatment of symptomatic ventricular premature contractions and tachycardia. However, the Cardiac Arrhythmia Suppression Trial (CAST) in patients with old myocardial infarction showed that class-I antiarrhythmic drugs have proarrhythmic effects, resulting in poor prognoses. So far, the arrhythmogenic mechanisms by the Na channel blockade are not well-known. Methods: To clarify this issue, we conducted simulations of action potential propagation in a myofiber model incorporating the electric field mechanism (taking into account the intercellular cleft potentials). Since it is recently reported that Na channels are confined to intercalated discs of surviving myocytes (lack of Na channels in lateral cell membrane) in the ischemic border zone, we incorporated the intracellular remodeling of Na channels into the model.
Results: We found that the intracellular remodeling of Na channels in myocytes located at ischemic border zone contributed to conduction slowing. In addition, conduction block tended to occur in the ischemic border zone when numerically administered Na channel blockade to the myofiber model, but this was not the case when the Na channels were distributed over the entire cell membrane.
Conclusion: Ischemia-induced intracellular remodeling of Na channels might be partly responsible for the proarrhythmic effects of Na channel blockade in patients with old myocardial infarction.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA015

Cardiac-targeted deletion of Cα subunit of PP2A in mice caused dilated cardiomyopathy with electrical remodeling

D. Dong[1], J. Liu[1], Z. Zhu[1], W. Chen[1], P. Gu[2], X. Gao[2] and Z. Zhang[1]

[1]Jiangsu the Key Laboratory for Molecular and Medical Biotechnology, College of Life Science, Nanjing Normal University, Nanjing, Jiangsu, China and [2]Model Animal Research Center, Nanjing University, Nanjing, Jiangsu, China

Reversible phosphorylation governed by kinases and phosphatases is a crucial post-translational modifications of the protein functions. Dysregulation of protein phosphorylation has been linked to a host of dysfunctional and arrhythmic heart diseases(1, 2). We have previously observed that the mice with cardiac-tagerted deletion of Cα subunit of PP2A (KO) generated with C57BL/6J mice by Gu et al(3), developed dilated cardiomyopathy at the postnantal day 11 and died around the day 13. The goal of present study was to analyse patterns of cardiac electrical remodeling in KO mice. The mice at 9 to 11 days after birth were anaesthetised with avertin (240 mg/Kg, i.p.) or phenobarbitol sodium (40mg/Kg, i.p.) for echocardiographic meaurements (n=3 respectively, for each group) or for the heart dessection. Values are means ± S.E.M, compared by Student's paired *t*.-test or ANOVA followed by a *q*. test. As compared to control, cardiac hypertrophy was evidenced by the increases in left ventricle to body weight ratio and left ventricle mass, by the significant elevation of mRNA expression for ANP, BNP and β-MHC, by the increase in both end of diastolic and end of systolic volumes for left ventricles as well as by the decrease in the fractional shortening and ejection fraction in KO mice ($P<0.05$). In addition to morphological changes observed in HE staining, notable ultrastructural alterations in KO myocytes were illustrated in TEM analysis. Moreover, electriophysiological recordings indicated that the duration of APs in KO myocytes were markedly prolonged as compared with those in control ($P<0.01$ KO vs control, n=9 and 7 cells, respectively, from at least 3 to 4 mice for each group). In contrast, no changes were observed in RPs and other parameters of APs. Consequently, a significant reduction of transient outward K^+ currents and intermediate increase of L-type Ca^{2+} currents were documented in KO myocytes ($P<0.05$ KO vs control, n=7 and 5 respectively). In consistence with changes in ion currents, an upregulation of Cav1.2, whereas down-regulations of Kv4.2, Kv4.3, Kv1.4 and KChIP2 proteins co-accembling α and β subunites of transient outward K^+ channel were detected by western blot analysis (from 3 independent expreiments). Importantly, the increased phosphorylation of Cav1.2 Ca^{2+} channels in KO mice was demonstrated by immunohistochemistry and western blot analysis in comparasion with those of control (n=3 for each, $P<0.05$). Taken together, these findings are indicative of the fundamental role of PP2A in the mouse heart and imply that loss of PP2A may disturbant Cav1.2 phosphorylation and intracellular Ca^{2+} concentration and then, causes cardiomyopathy along with electrical remodeling.

The role of fibre orientation in cardioversion of chronic atrial fibrillation: a simulation study

S.R. Kharche[1], T. Stary[1], I.V. Biktasheva[2], H. Zhang[3] and V.N. Biktashev[1]

[1]Department of Applied Mathematics, College of Engineering, Mathematics and Physical Sciences, University of Exeter, Exeter, UK, [2]Department of Computer Science, University of Liverpool, Liverpool, UK and [3]Department of Physics, University of Manchester, MANCHESTER, LANCS, UK

Fiber orientation anisotropy in the human atria influences the success of electrical cardioversion. This computational study quantifies the effectiveness of a feedback controlled cardioversion method [1] using a novel cardiac simulation environment, BeatBox [2].

A biophysical human atrial cell model [3] was adopted to simulate Control and chronic atrial fibrillation (CAF) action potentials (APs). Electrophysiological alterations due to CAF were simulated as described previously [4]. The cell model was combined with human atrial geometry with fiber orientation to construct a 3D realistic human atrial model. Scroll waves were initiated using a phase distribution method and allowed to evolve for 10 s. The cardioversion parameters [1] of threshold stimulus and low energy stimulation strength required for scroll wave termination were evaluated. Scroll waves were initiated at two sites to elicit the effects of scroll wave location. The obtained results were compared a previous isotropic case study [5].

CAF reduced the AP from 306 ms to 120 ms (Fig 1, A). Scroll waves were initiated at two locations and the electrical activity registered at a point registration electrode (Fig 1, B). Under CAF isotropic conditions, the scroll waves became pinned (Fig 2, A). In contrast, anisotropy caused the scroll wave to degenerate into multiple scrolls with each scroll evolving erratically or pinning to anatomical defects (Fig 2, A). Recurrence cycle maps (Fig. 2, B) show that under CAF isotropy leads to a monomorphic tachycardia while with anisotropy gives rise to a polymorphic tachycardia. The single shock stimulation threshold to eliminate CAF scroll waves was found to be 4.5 pA/pF. For CAF scroll waves initiated at location L1 (Fig 1, B), a series of small amplitude global stimuli of strength 0.4 pA/pF were sufficient in terminating the scroll waves. However CAF scroll waves initiated at L2 required a minimum stimulation strength of 2 pA/pF for termination within 10 s. In all CAF simulations, the localized pacing at the registration electrode was approximately 8 Hz.

Inherent atrial anisotropy plays an important role in atrial electrical properties. The low energy stimulus strength has a strong correlation to the scroll wave location. The low energy stimulation strength was always lower than the threshold stimulus. Anisotropy aggravates CAF and leads to high frequency erratic propagations. The efficacy of cardioversion is significantly affected by anatomical defects as well as anisotropy. The novel multifunction simulation package, BeatBox, is an ideal simulation environment that facilitates such extensive large scale simulation studies.

PCA018

Simulating cell apoptosis induced sinus node dysfunction

S.R. Kharche[1], T. Stary[1], I.V. Biktasheva[2], H. Zhang[3] and V. Biktashev[1]

[1]CEMPS, University of Exeter, Exeter, UK, [2]Computer Science, University of Liverpool, Liverpool, UK and [3]Physics, University of Manchester, MANCHESTER, LANCS, UK

Sinus node dysfunction (SND) is a known cause of bradycardia, sinus arrest, and sinus pause, and leads to subnormal atrial pacing. Experimental evidence shows that SND is correlated to the pacemaker sinoatrial node (SAN) cell apoptosis [1]. The effect of such a dysfunctional SAN on electrical propagation into neighboring atrial tissue remains under explored. A novel computational cardiology simulation environment, BeatBox [2], which provides a versatile computational tool to develop and construct simulation models and was used in this study.

The computationally efficient Fenton-Karma (FK) model [3] was extended to simulate mouse SAN and atrial cell action potentials (APs). To simulate atrial AP, the basal model parameters [3] were altered. Further, a hyperpolarisation activated current was incorporated into the basal model, and then the parameters altered to simulate the SAN pacemaking AP. The cell models were incorporated into a 2D model consisting of a central SAN region surrounded by atrial tissue. In each 2D simulation, 10 s of electrical activity were simulated. First, the basal size of mouse SAN pacemaking region was estimated using the 2D model. Then in multiple simulations, SAN cell apoptosis was simulated by randomly eliminating a proportion of SAN cells from the pacemaking region. The effects of an increasing proportion of apoptotic pacemaker cells on atrial tissue pacing were simulated and quantified.

The modified FK model that reproduces SAN and atrial APs as well as validation with experimental observations is shown in Fig. 1. The SAN size that gave a basal mouse atrial cycle length (ACL) of 295 ms was found to be 0.6 mm in radius. In the simulations where pacemaker cell apoptosis was considered (Fig. 2), a more dramatic effect was seen. At low pacemaker cell apoptosis proportion, there was a drastic increase of ACL. At modest increase in the number of apoptotic cells, bradycardia was observed. The incidence of sinus arrest was also found to be high. When the numbers of apoptotic cells were 10% of the total number of pacemaking cells, all pacemaking was arrested. Our computational findings agree with recent experimental results [1].

Novel phenomenological models have been developed to facilitate the study of mouse atrial electrophysiology as well as tissue behaviour. The results show the significance of cell apoptosis as a major mechanism of SND. Novel computational modules in the simulation environment were developed to enable this study. BeatBox is an ideal computational environment to conduct such large scale studies.

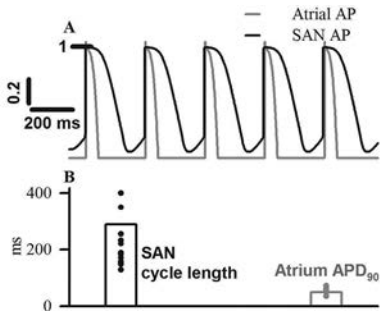

Fig 1. Simulated APs using the modified FK models. A: AP profiles of mouse SAN (solid line) and mouse atrial (gray line) cell types. B: Validation of SAN cycle length and atrial APD90. Symbols show experimental data and bars show simulation results. The experimental data was taken from a previous study [4].

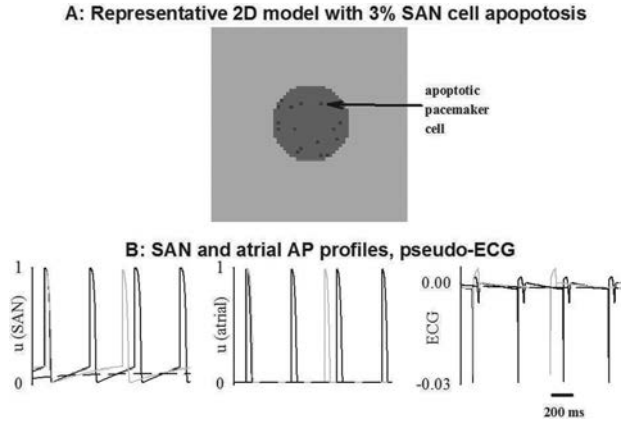

Fig. 2. A: Atrial (light gray), SAN (dark gray), and apoptotic cells (black) in the 2D idealized model. B: Representative SAN APs (left panel), atrial APs (middle panel), and pseudo-ECG profiles from the 3% apoptosis simulation. Out of the 50 run population, the APs shown are ACL = 400 ms (black lines in all 3 panels), ACL = 800 ms (gray lines), and a SAN arrest case (dashed black lines).

Effects of diabetes mellitus and exercise training on expression of mRNA, contraction and calcium transport in the adult Goto-Kakizaki rat heart

F.C. Howarth[1], K.A. Salem[1], M.A. Qureshi[1], V. Sydorenko[1], K.A. Parekh[1], P. Jayaprakash[1], T. Iqbal[2], J. Singh[2], M. Oz[3] and T.E. Adrian[1]

[1]Physiology, UAE University, Al Ain, United Arab Emirates, [2]School of Pharmacy & Biomedical Sciences, University of Central Lancashire, Preston, UK and [3]Pharmacology, UAE University, Al Ain, United Arab Emirates

The prevalence of diabetes mellitus (DM) in the United Arab Emirates is among the highest in the world. Hearts of diabetic patients are frequently in a compromised condition. A variety of diastolic and systolic dysfunctions have been reported in patients with type 2 diabetes mellitus (T2DM). Although, several novel forms of intervention aiming at newly identified therapeutic targets are being developed for T2DM it is well established that physical exercise continues to be one of the most valuable forms of non-pharmacological therapy. An abundance of evidence exists for prescribing exercise therapy in the treatment of various diseases including metabolic syndrome-related disorders, heart and pulmonary diseases. Physical activity has been reported to influence several aspects of DM including blood glucose concentrations, insulin action and cardiovascular risk factors and long-term exercise has been repeatedly associated with lower rates of T2DM. The effects of DM and exercise training on expression of mRNA encoding cardiac muscle proteins and on ventricular myocyte contraction and intracellular Ca2+ transport in the adult Goto-Kakizaki (GK) type 2 diabetic rat was investigated. Experiments were performed in GK and control rats aged 10-11 months following 2-3 months of treadmill exercise training. Expression of mRNA was assessed in ventricular muscle with real-time RT-PCR. Shortening, intracellular free Ca2+ and L-type Ca2+ current were measured in ventricular myocytes with video edge detection, fluorescence photometry and whole cell patch clamp techniques. Non-fasting blood glucose was elevated in GK compared to age-matched controls and exercise slightly reduced blood glucose in control and more so in GK rats. Expression of mRNA encoding cardiac muscle, intercellular, cell membrane transport, calcium and potassium channel proteins were variously altered in GK and control rats and with exercise. Expression of Tpm2, Gja4, Atp1b1, Cacna1g, Cacnb2, Hcn2, Kcna3 and Kcne1 were up-regulated and Gja1, Kcnj2 and Kcnk3 were down-regulated in heart of GK rats compared to sedentary controls. Gja1, Cav3 and Kcnk3 were up-regulated and Hcn2 was down-regulated in hearts of exercise trained GK compared to sedentary GK controls. Amplitudes of shortening, Ca2+ transients and L-type Ca2+ current were not significantly altered in ventricular myocytes from GK rats compared to sedentary controls or by exercise training. Despite alterations in the profile of expression of mRNA encoding a variety of cardiac muscle proteins in the GK rat and as a result of exercise training, ventricular myocyte shortening and Ca2+ transport were generally well preserved in the adult GK diabetic rat heart.

PCA020

AT1 receptor blockade by irbesartan attenuates hyposmostic-induced increase of IKs current and prevents shortening of APD in guinea-pig atrial myocytes

J. Wu[1,3], W. Ding[2], J. Dou[1], H. Matsuura[2] and M. Horie[3]

[1]Medical School of Xi'an Jiaotong University, Xi'an, Shaanxi, China, [2]Physiology, Shiga University of Medical Science, Otsu, Shiga, Japan and [3]Cardioascular and Respiratory Medicine, Shiga University of Medical Science, Otsu, Shiga, Japan

The shortening of action potential duration (APD) and effective refractory period (ERP) are generally regarded as pivotal factors for the occurrence of reentry-based atrial fibrillation (AF). During AF, impaired atrial contraction causes the atria to dilate or stretch and induce the secretion of Ang II from cardiomyocytes. Stretch of the atrial membrane up-regulates the slow component of delayed rectifier K+ current (IKs). Blockade of angiotensin II subtype 1 receptors (AT1R) attenuates this increase in IKs. The present study aimed to examine effects of irbesartan, a selective AT1R blocker (ABR), on both the enhancement of IKs and the shortening of action potential duration (APD) induced by stretching atrial myocytes for exploring the mechanisms underlying the prevention of AF by ABR. Adult female Hartley guinea pigs (weighing 250-350g) were anaesthetized with pentobarbital sodium (80 mg kg-1, I.P.) and single atrial myocytes were enzymatically dissociated from the hearts of using a retrograde Langendorff perfusion method. Hyposmotic solution (Hypo-S) was used to stretch guinea pig atrial myocytes. IKs and APD were recorded using the whole-cell patch-clamp technique. Values are means ± S.E.M., compared by one-way ANOVA with Newman-Keuls post-hoc test. The result shows that therapeutically-relevant concentrations of irbesartan (1-50 μM) attenuated the Hypo-S-induced increase (but not baseline) levels of atrial IKs and shortening of APD90. Hypo-S increased the IKs by 113.4±9.96% (n = 18), whereas Hypo-S + 1 μM irbesartan and Hypo-S + 50 μM irbesartan only increased the IKs by 74.5±8.49% (n = 10; $p < 0.05$ vs. Hypo-S) and 70.3± 9.34% (n = 16; $p < 0.05$ vs. Hypo-S), respectively. In addition, Hypo-S shortened the APD90 by 19.03±1.36% (n = 17), whereas Hypo-S + 1 μM irbesartan and Hypo-S + 50 μM irbesartan shortened the APD90 by 12.05 ± 1.38 (n = 9; $p < 0.01$ vs. Hypo-S) and 12.0 ± 1.46 (n = 14; $p < 0.01$ vs. Hypo-S), respectively. The above data suggest that actions of irbesartan on electrical changes induced by stretching atrial myocytes are associated with blocking AT1R and may be beneficial for treating AF that is accompanied by atrial dilation and prolongation of the effective refractory period.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA021

Implication of myocardial connexin-43 and PKC signaling in cardio-protective effects of melatonin in spontaneously hypertensive rats

N. Tribulova[1], T. Benova[1], C. Viczenczova[1], J. Radosinska[1], B. Bacova[1], V. Knezl[2], V. Dosenko[3] and M. Zeman[4]

[1]Institute for Heart Research, SAS, Bratislava, Slovakia, [2]Institute for Experimental Pharmacology, SAS, Bratislava, Slovakia, [3]Bogomoletz Inst. of Physiology, Kiyv, Ukraine and [4]Faculty of Natural Sciences Comenius University, Bratislava, Slovakia

Background and Purpose: Experimental and human studies indicate that melatonin may regulate blood pressure and suggest the potential use of melatonin as adjunct antihypertensive therapy. However, melatonin levels have been shown decreased in patients treated with beta-adrenergic blockers as well as in spontaneously hypertensive rats (SHR). We aimed to examine whether treatment with melatonin will affect propensity of SHR heart to malignant arrhythmias and electrical coupling protein, connexin-43 (Cx43).
Design and Methods: SHR and healthy Wistar rats fed a standard rat chow received orally melatonin (40 mikrog/ml) for 4 weeks and were compared with untreated rats. Systolic blood pressure (BP), plasma cholesterol (CH), triglycerides (TG) and blood glucose (BG) were registered at the end of experiment. Myocardial Cx43 mRNA level was determined by real time PCR, while the expression of Cx43 protein, protein kinase C (PKC) epsilon and delta by western blots. Isolated Langendorff-perfused heart was used to test its susceptibility to electrically inducible ventricular fibrillation (VF).
Key Results: Melatonin significantly reduced BP (180+24 vs 206+10 mmHg) and normalized TG but did not affect body, heart and left ventricular weights in SHR. Compared to healthy rats the threshold to induce sustained VF was lower in SHR (18.7+2 vs 29.0+5 mA, $p<0.05$) and significantly increased in melatonin-treated SHR to 33.0+4 mA. Myocardial Cx43 mRNA levels did not differ from healthy rats but total Cx43 protein was decreased in SHR heart left ventricle. In contrast, melatonin treatment resulted in a significant increase of both Cx43 protein and mRNA in SHR as well as healthy rats. Moreover, melatonin normalized myocardial PKC-delta expression and enhanced PKC-epsilon in SHR as well as healthy rat hearts.
Conclusions: Results indicate antiarrhythmic effects of melatonin in hypertensive rats that can be, in part, attributed to up-regulation of myocardial Cx43 and PKC signaling. Findings support monitoring of melatonin levels and its supplementation in patients with CVD.

Heart failure in diabetes mellitus (DM) is a major cause of premature morbidity and mortality but the underlying mechanisms are elusive and treatment remains empirical. Previously, we reported significant voltage-dependent decreases in force of contraction and L-type calcium current channel activities in the streptozotocin (STZ)-induced diabetic heart. This study now investigated how DM via hyperglycaemia (HG) can induce histopathological changes in the left ventricle (LV) of STZ-treated type 1 diabetic male Wistar rats compared to age-matched controls, six-eight weeks following STZ-administration (60 mg/kg body weight). The study was approved by the Home Office and UCLAN Ethics Committee. A portion of the LV underwent processing for histological studies employing the Haematoxylin and Eosin stain, labelling with FITC-conjugated Lectin and the Masson's trichrome stain for determination of myocyte size and quantitative assessment of fibrosis, respectively. Immunohistochemical studies were conducted to assess the contribution of diabetes towards activation of apoptotic pathways governed by caspase-3.
STZ-treated rats presented with significantly (Student's t-test; $p<0.01$) higher blood glucose values (305.86± 7.48 mg/dl, n=6) relative to controls (89.51±3.56 mg/dl, n=6) and significantly ($P<0.05$) reduced body (232.33±11.07 g) and heart (0.55±0.03 g) weights compared to controls (301.20±16.31 g for body and 0.94±0.05±0.05 g for heart, n=6). Similarly, heart to body mass ratio (g/100 g body weight) was significantly ($P<0.05$) less in the diabetic animals (0.24± 0.02, n=6) compared to control (0.31± 0.02, n=6). LV morphology was also severely altered by DM. Morphometric analysis indicated significant ($P<0.05$) increments in fibrous tissue proliferation (5.05±0.44% vs 3.51±0.44%, n=6) and smaller myocyte transverse diameter in the diabetic heart compared to control. The heart was also atrophied and STZ-treated animals presented with lower heart weights and heart weight to body weight ratios relative to controls ($p<0.01$). In STZ-treated LV, the pathology frequently manifested as focal scarring, myofibrillar loss, vacuolisation and large clusters of cells showing histological signs of apoptosis. Activity of cleaved caspase-3 was also significantly ($p<0.01$) increased in the STZ-treated group. The results indicate that STZ-induced type-1 DM results in the development of a cardiac disease characterised by LV histopathological changes consistent with a dominant influence of HG and underlying alterations in insulin action.

Fibrosis and downregulation of Ca^{2+}-handling proteins as an underlying cause of cardiac repolarisation alternans and sudden cardiac death in the human

J. Yanni[1], P. Lambiase[2], M. Orini[3], B. Hanson[3], H. Dobrzynski[1], X. Jie[3], M. Boyett[1], M.P. Hayward[3] and P. Taggart[3]

Repolarisation alternans has been found to be predictive of or precede lethal ventricular arrhythmias in cardiac patients, as well as in the laboratory. Alternans is believed to cause arrhythmias by enhancing the regional physiological heterogeneities within normal cardiac tissue, to the point where functional conduction blocks develop, to initiate re-entrant arrhythmias. Using qPCR, immunohistochemistry and western blot (to confirm the specificity of antibodies), this study investigated the expression of ion channels and extracellular matrix (mRNAs and proteins) in areas of ventricular tissue displaying cardiac alternans & non-alternans sites. Epicardial samples were obtained from 19 patients who were undergoing elective surgery primarily for ischaemic heart disease. During the surgery, the patient's heart was mapped using an epicardial sock which contained 256 electrodes. The heart was then paced at fixed cycle lengths to induce alternans. Activation Recovery Intervals (ARI), a surrogate for action potential duration (APD), was estimated and repolarisation alternans was quantified by an index incorporating both extent and persistence of beat-to-beat variations in ARI. Two myocardial biopsies were taken for mRNA analysis, each from sites of maximum and zero repolarisation alternans. The criterion for alternans was ≥ 6 consecutive beats of alternans with a steady state drive train of ventricular pacing at between 600-350 ms cycle length for 30 seconds each (50 ms reduction in cycle length between drive trains). Vimentin mRNA, which is a fibroblast marker, and collagen type 1 mRNA, which constitutes ~80% of total collagen mRNA, showed positive correlations with repolarisation alternans (R^2 of 0.76 and 0.86 for vimetin and collagen type I, respectively). KChIP2 mRNA showed a positive correlation with repolarisation alternans (R^2=0.82), whereas SERCA2 mRNA showed a negative correlation with repolarisation alternans (R^2=0.82). A possible explanation is that there are areas of micro-infarction in the ventricle and this causes fibrosis accompanied by a downregulation in KChIP2 and SERCA2 which contribute to the production of repolarisation alternans. These micro-infarcts may, therefore, be responsible for arrythmogenesis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Cardioprotection of Hydrogen sulfide post-conditioning against ischemia reperfusion injury involved in ATF6 activated endoplasmic reticulum stress -induced apoptosis

X. Yan, J. Deng, T. Chen, Y. Wang, Z. Wang and Y. Ding

Department of Physiology, Wuhan University school of basic medical sciences, Wuhan, China

Endogenous hydrogen sulfide (H2S) was involved in myocardial ischemia postconditioning and alleviated ischemia-reperfusion (I/R) injury, and exogenous H2S postconditioning has a protective effect on the isolated heart I/R injury. Myocardial I/R can induce endoplasmic reticulum stress (ERS), and excessive ERS will induce apoptosis and increase the myocardial injury. Recently, studies have shown that ATF6 is activated in myocardiaocytes by ER stress. In the present study, we determined whether H2S post-conditioning protection myocardium from I/R injury involved in ATF6 activated ERS. Sprague-Dawley rats (male, 250-300g) were anaesthetised with urethane (1g kg-1 i.p.) and were randomly divided into 5 groups (n= 12 in each): Sham group, I/R group, I/R+NaHS groups (H2S post-conditioning group), I/R+TUDCA (Tauro Ursodesoxy Cholic Acid, an ERS blocker) group and I/R+TUDCA+NaHS group. NaHS 14μmol/kg and TUDCA 25mg/kg were injected i.p. after 30min of myocardial ischemia and within reperfusion 10 min. The myocardial I/R rats were subjected to ischemia by 30 min of coronary artery branch of left anterior descending occlusion followed by 2 h of reperfusion. At the end of the reperfusion, myocardial infarct size was examined by triphenyltetrazolium chloride (TTC) staining, serum concentration of H2S was determined with a spectrophotometer, myocardial apoptosis was detected by TUNEL and the protein levels of ATF6, GRP78, PDI, and CHOP were assayed by western blotting. At the end of reperfusion, the average myocardial infarct size was 37.41±3.3%. Compared with the Sham group, the H2S concentration in the serum of the I/R group was significantly decrease (24.98±0.69 vs 44.56±0.86μmol/L, P<0.01); the myocardiaocytes apoptotic rate were significantly increased (84.28±3.03% vs 0.50±0.29%, P<0.01); the endoplasmic reticulum stress related proteins ATF6, GRP78, PDI and CHOP expression level in myocardial tissue were significantly increased (P<0.01). Compared with I/R group, serum H2S concentrations of I/R+NaHS group were significantly increased (43.48±2.31 vs 24.98±0.69μmol/L, P<0.01). Administration of exogenous H2S into rat /H2S post-conditioning could decrease myocardial infarct size (18.69±1.87% vs 37.41±3.3%, P<0.01) and myocardiocytes apoptotic rate (34.23±2.92% vs 84.28±3.03%, P<0.01) significantly. The decrease of ATF6, PDI, GRP78 and CHOP protein level in I/R could be partly reversed by H2S post-conditioning (P<0.05). Using TUDCA to block ER stress could also attenuate I/R injury; compared with I/R+TUDCA group, I/R+NaHS group had even stronger protecting effect on myocardial infarct size and apoptosis rate. This finding suggested that cardioprotection of H2S postconditioning may involve inhibiting apoptosis caused by ATF6 activated excessive ERS induced by myocardiac I/R.

An extra-mitochondrial domain rich in carbonic anhydrase activity improves myocardial energetics

M.A. Schroeder[1], M.A. Ali[1], A. Hulikova[1], C.T. Supuran[2], K. Clarke[1], R.D. Vaughan-Jones[1], D.J. Tyler[1] and P. Swietach[1]

[1]Department of Physiology, Anatomy and Genetics, Oxford University, Oxford, UK and [2]Dipartimento di Scienze farmaceutiche, Università degli Studi di Firenze, Florence, Italy

The heart's intensive pumping activity is powered by a uniquely high rate of mitochondrial respiration. This generates vast quantities of the waste-product CO_2, which must be removed efficiently from mitochondria. Carbonic anhydrase (CA) enzymes, expressed at various sites in ventricular myocytes, may affect mitochondrial CO_2-clearance by catalyzing CO_2 hydration (to H^+ and HCO_3^-) thereby changing the gradient for CO_2 venting. In this study, we measured CA activity in cardiac myocytes, and investigated the effects of CA inhibition on cardiac energetics and function.

CA activity in the cytoplasm of isolated ventricular myocytes was measured by fluorescence imaging of cells loaded with the pH reporter dye, cSNARF1 (10 μM, AM-loading for 5 min). Rapid exposure to CO_2-containing solution evoked CO_2 entry and its intracellular hydration which was only modestly accelerated by CA activity (2.7±0.3[SEM]-fold above spontaneous kinetics determined in the presence of the broad-spectrum CA inhibitor acetazolamide, ATZ, 100 μM). A similar experiment performed on isolated ventricular mitochondria demonstrated negligible intra-mitochondrial CA activity. CA activity was also investigated in intact hearts by ^{13}C magnetic resonance spectroscopy (MRS) from the rate of $H^{13}CO_3^-$ production from $^{13}CO_2$ released specifically from mitochondria by pyruvate dehydrogenase-mediated metabolism of hyperpolarized [1-^{13}C]pyruvate. Under these conditions, the steady-state between de novo production and capillary wash-out produces a gradient of $^{13}CO_2$ from mitochondria to the sarcolemma. CA activity measured upon [1-^{13}C]pyruvate infusion was 11.4±0.9 fold above spontaneous kinetics (i.e. four-fold higher than the cytoplasm-averaged value).

A fluorescent CA-ligand (fluorescein-thioureido-homosulfanilamide) co-localized with the mitochondrial marker TMRE (Pearson's coefficient 0.735±0.06), indicating that mitochondria are near a CA-rich domain. Based on immunoreactivity, this domain comprises the nominally cytoplasmic CAII and sarcoplasmic reticulum-associated CAXIV. Inhibition of extra-mitochondrial CA activity with ATZ acidified the matrix by up to 0.1 unit (pH 7.73±0.03 to 7.62±0.02 measured by fluorescence imaging of permeabilized myocytes and isolated mitochondria by flow cytometry), impaired cardiac energetics (phosphocreatine-to-ATP ratio decreased from 2.02±0.13 to 1.58±0.14, measured by ^{31}P-MRS of perfused hearts) and reduced contractility (developed pressure in perfused hearts decreased by 18±5%). These data provide evidence for a functional domain of high CA activity around mitochondria to support CO_2-venting, particularly during elevated and fluctuating respiratory activity. Aberrant distribution of CA activity may therefore reduce the heart's energetic efficiency.

A new experimental approach reveals a high Ca^{2+} sensitivity of TRPM4 channel and its significant implications in arrhythmogenicity

R. Inoue, Y. Hu, Y. Duan, R. Kurahara-Hai and J. Ichikawa

Department of Physiology, Fukuoka University School of Medicine, Fkuoka, Fukuoka, Japan

TRPM4 is a molecular correlate for Ca^{2+}-activated monovalent cation selective channels ubiquitously expressed in both excitable and non-excitable tissues. Recent investigations have revealed that increased expression of this channel protein may be the main causes for certain types of familial atrio-ventricular blocks and other arrhythmogenic propensity associated with cardiac remodeling. However, the apparent Ca^{2+} sensitivity of this channel evaluated in heterologous systems is almost out of physiological range (typically >10μM), so that it remains still puzzling how exactly it could contribute to arrhythmogenicity. In this study, we re-evaluated the Ca^{2+} sensitivity of TRPM4 channels in both expression systems and immortalized atrial cardiomyocyte cell line HL-1, and explored their roles in inducing arrhythmic changes by means of mathematical model simulations.
In cell-free conditions, the Ca^{2+} sensitivity of human TRPM4 channels expressed in HEK293 cells rapidly declined requiring more than several-hundred μM Ca^{2+} for half maximal activation (K_d) near the resting membrane potential. However, a much higher Ca^{2+} sensitivity was observed when cells were maintained as intact as possible and intracellular Ca^{2+} concentration was changed via ionomycin-mediated Ca^{2+} influx (K_d: ~ 0.5μM). A similar estimate of K_d was obtained in experiments evaluating the relationship between the integral of voltage-dependent Ca^{2+} influx and the magnitude of tail cationic current in HEK cells coexpressing TRPM4 and voltage-dependent Ca^{2+} channels (VDCC) subunits (α1C/β2/α2δ). Furthermore, repetitive activation of VDCC at high frequencies induced the development of sustained TRPM4 current at -80mV. 4-5 day treatment of HL-1 myocytes with angiotensin II resulted in enhanced expression of TRPM4 channel protein and current density, and induced spontaneous action potentials (APs) with prolongation of AP duration, which could be abolished by a relatively selective concentration (10μM) of a TRPM4 channel blocker, 9-phenanthrol. In silico simulation of cardiac action potentials (APs) based on 2000 Luo-Rudy or Nygren models which incorporated the Ca^{2+}- and voltage-dependent kinetics of TRPM4 channel reproduced the late phase-3 AP prolongation and moderate basal depolarization when increasing the expression level of TRPM4 by several fold.
These results suggest that the intact Ca^{2+} sensitivity of TRPM4 channel would be sufficiently high to induce arrhythmic changes, when the channel expression or function is up-regulated.

Intrinsic left atrial histoanatomy as the basis for reentrant excitation causing atrial fibrillation/flutter in rats

T. Matsuyama[2,1], H. Tanaka[1], T. Adachi[1], Y. Jiang[1], H. Ishibashi-Ueda[2] and T. Takamatsu[1]

[1]Pathology and Cell Regulation, Kyoto Prefectural University of Medicine Graduate School of Medical Science, Kyoto, Japan and [2]Pathology, National Cerebral and Cardiovascular Center, Osaka, Japan

In contrast to the pulmonary veins as a well-accepted site for triggering paroxysmal atrial fibrillation/flutter (AF/AFL), little is known about the intrinsic basis for reentrant excitation in persistent AF/AFL. To explore histoanatomic substrates for reentrant AF/AFL in atria, we conducted functional and histoanatomic studies of the whole atria of rats by combining optical imaging of impulse propagation with histologic examination. After sufficient general anaesthesia applied to male Wistar rats (n=19, 11-14 weeks, 290–430 g) by single intraabdominal injection of sodium pentobarbitone (19 mg/100g), hearts with bilateral lungs were excised and were quickly perfused in a Langendorff manner. Spatiotemporal patterns of impulse propagation were visualized optically on the posterior surface of the atria stained with di-4ANEPPS at 32 °C with cytocholasin D (4 μmol/L). AF/AFL was evoked by single extra stimulation (S2) after 5-Hz consecutive pacing (S1) at the right atrium (RA). After the optical imaging we quantified regional differences in 3 histological determinants for conductivity, i.e., myocardial density, myofibre orientation, and distribution of gap junctional (connexin 43) proteins (n = 10). The myocardial density was evaluated by Masson's trichrome staining, and other two parameters were assessed by confocal immunohistochemistry. Quantitative data (mean±SD) were analysed by paired t-test or one-factor ANOVA. Burst (S1-S2) pacing at the RA provoked AF/AFL in 15 of 19 hearts, and most cases developed by organized reentrant excitation through the coronary sinus (CS) and left atrium (LA) roof, with non-organized irregular propagation in 3 cases. The reentrant circuit developed along 2 directions of propagation in the LA: a slower one at the LA roof and a faster one along the CS, with conduction velocities of 42.4±16.6 cm/s and 53.3±9.2 cm/s, respectively ($p<0.005$). Upon S2 stimulus the impulse at the LA roof propagated retrogradely from the CS, resulting in reentrant propagation that mediated through the CS and the LA roof. Histologic quantification revealed significantly lower myocardial density in the posterior LA and the septum than in the remainder of the atria, suggesting a possible electrical obstacle. Moreover, myocytes in the LA roof were significantly of lower density ($p<0.005$) and arranged more randomly in the direction of conduction than those in the CS. Connexin 43 plaques were distributed randomly over the entire cell membrane in the LA roof (slower pathway), whereas those in the CS (faster pathway) were located in orderly fashion. We identified an intrinsic histoanatomic basis in the LA, especially the posterior LA, septum and LA roof, for formation of reentrant propagation in the atria. These regional heterogeneities observed in the LA would constitute a pro-reentrant substrate for perpetuating AF/AFL.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Altered thyroid status affects myocardial connexin-43 and PKC expression in male and female Wistar rats: effect of antioxidant-rich red palm oil intake

B. Bacova[1], C. Viczenczova[1], J. Radosinska[2], J. Zurmanova[3], S. Pavelka[4], T. Soukup[4], J. van Royen[5] and N. Tribulova[1]

[1]Institute for Heart Research, SAS, Bratislava, Slovakia, [2]Institute of Physiology, Faculty of Medicine, Comenius University, Bratislava, Slovakia, [3]Faculty of Science, Charles University in Prague, Prague, Czech Republic, [4]Institute of Physiology, v.v.i., AS CR, Prague, Czech Republic and [5]Cape Peninsula University of Technology, Bellville, South Africa

Background and purpose: The cardiovascular system is modulated by thyroid hormones and their deficiency or excess in hypo- (HY) or hyperthyroid (TH) status may affect both cardiac function and arrhythmogenesis. We hypothesized that intercellular communication via connexin-43 (Cx43) channels might be implicated. The goal of this study was to explore myocardial Cx43 and PKC expression in rats with altered thyroid status as well as the effects of antioxidant-rich red palm oil (RPO) intake.
Design and Methods: Male and female 4-month-old Wistar euthyroid rats (EU); HY rats (treated with 0.05% methimazole); TH rats (treated with T3/T4, 5/25 μg/100g b.w./day) fed with RPO (100 microL/100g b.w./day) for six weeks were compared with untreated rats. Left ventricular tissue was taken for Cx43 and PKC-epsilon mRNA and protein analysis using Real Time PCR and immunoblotting.
Key Results: Heart and left ventricular weights were significantly increased in male and female TH and decreased in HY rats compared to EU rats. Cx43 mRNA level was increased in male, but not in female TH rats and decreased in HY rats regardless of sex. In contrast, Cx43 protein and its functional phosphorylated (P) forms were increased in HY, but decreased in TH rats of both sexes. PKC-epsilon gene expression did not change in male, but decreased in female TH rats whereas it increased in male, but not in female HY rats. PKC-epsilon protein expression was decreased in male, but not in female TH rats and increased in HY rats regardless of sex. RPO intake reduced heart and left ventricular weight in TH rats; partially normalized Cx43 mRNA as well as protein expression and its P forms in male and female TH and HY rats; normalized PKC-epsilon protein expression in male TH rats.
In conclusion, our findings indicate sex-related differences in Cx43 and PKC-epsilon gene expression due to altered thyroid status. In general, there is a down-regulation of myocardial Cx43 and PKC-epsilon in hyperthyroidism, while up-regulation in hypothyroidism. RPO intake attenuated abnormalities of Cx43 and PKC-epsilon expression.

PCA030

Spermine reduced no-reflow size induced by ischemia-reperfusion through regulating autophagy

H. Liping, Y. Linbo, S. Yangping and S. Jundan

Physiology, Wenzhou Medical College, Wenzhou, China

Background: No-reflow (NR) phenomenon is a risk factor which severely compromises the benefits of coronary revascularization in patients with acute myocardial infarction. It has been found that autophagy increased after IR, and it seems that modest levels of autophagy appear to be protective. Our previous researches showed that the myocardial IR caused significant change of polyamine metabolism, and exogenous spermine protected the neonatal rat cardiomyocytes against anoxia-reoxygenation injury (ARI). The present study was undertaken to see whether exogenous spermine had protective effects against acute myocardial IR injury in vivo rat model, whether it reduced the myocardial no-reflow size and whether autophagy were involved in the protective effect.
Methods: Thirty SD rats weighing 250-300g were equally randomized to three groups: Sham control group, where the rats were treated with thoracotomy only; ischemia reperfusion (IR) group, where the rats were treated with ischemia for 40 min and reperfusion for 60 min; and spermine (SP) group, where 0.5mmol/L spermine (2ml/kg, i.v.) were given just 15min before reperfusion. The cardiac troponin I (cTnI) and creatine kinase isoenzyme (CK-MB) activities in serum were determined. NR size of the myocardium was measured by using Evan's blue and thioflavin S staining. Inflammatory response was detected by myocardial tissue myeloperoxidase (MPO) assay. And autophagy function was detected by measuring expression of Beclin-1 through Western blot.
Results: Spermine decreased serum cTnI and CK-MB levels, and reduced the IR-induced NR size of the left ventricle. Tissue MPO assay showed that myocardial inflammatory response was attenuated by spermine compared with IR. Western blot showed that Beclin-1 was up-regulated by spermine compared with IR group.
Conclusion: By up-regulating autophagy, exogenous spermine attenuated inflammatory response during myocardial IR, which contributed to reduce IR-associated NR size. Therefore, exogenous spermine or induce endogenous spermine might be a promising approach to prevent NR in patient with acute myocardial infarction (AMI) underwent reperfusion.
Animal care
All animal experiments were approved by the Animal Research Ethics Committee of the Wenzhou Medical College, Wenzhou, China. The investigation conformed with the guide for the care and use of laboratory animals published by the US National Institutes of Health. The whole procedures were performed under anaethesia.

PCA031

Generation of reentrant arrhythmias by spatially non-uniform gap-junction connection with myofibroblasts in rat cultured myocyte monolayers

T. Adachi, Y. Jiang, H. Tanaka, E. Hashimoto and T. Takamatsu

Department of Pathology and Cell Regulation, Kyoto Prefectural University of Medicine, Kyoto, Japan

Cardiac myofibroblasts (MFs) have recently been regarded as important in arrhythmogenesis. There is growing evidence that coupling of cardiomyocytes (CMs) with MFs in vitro alters impulse propagation via electrotonic effect by MFs. However, exact initiating mechanisms of the MF-mediated arrhythmia remain elusive because studies on the arrhythmogenesis have been conducted mostly on mixed co-cultured monolayers of CMs with MFs. **On the hypothesis** that spatially non-uniform coupling of CMs with MFs is requisite for reentrant arrhythmogenesis, we analysed spatiotemporal changes in impulse propagation of the CM monolayer cultured on a filter membrane (25-mm diameter; pore diameter, 8 μm; pore density, $6x10^5$ /mm^2) with culture of either MFs or CMs on the reverse side. CMs and MFs were obtained from neonatal rat hearts excised under generalised anaesthesia by i.p. injection of sodium pentobarbitone (0.2mg/g body wt). CMs ($2x10^5$ cells/cm^2) were plated on the upper membrane layer, and either CMs ($2x10^5$ cells/cm^2, CM/CM model) or MFs ($2x10^4$ cells/cm^2, CM/MF model) were plated on the reverse side. After 5-day culture, spatiotemporal changes in fluo-4-fluorescence (11x7mm, 192x128 pixels, 200 frames/s) were imaged on the confluent CM monolayers on the upper side at 33°C. Data (mean±SD), statistically analysed by ANOVA, were considered as significant at $p<0.05$. **We found** that during 2-Hz pacing at the margin of the upper layer, CMs exhibited uniform wavefronts from the pacing site in the CM/CM model with CV of 76.6±10.9mm/s (n=20), whereas those in the CM/MF model exhibited irregular wavefronts with slower CV (51.8±12.2mm/s, n=23, $p<0.01$). Gap-junction coupling between the upper and lower layers was demonstrated by calcein-dye transfer and its inhibition by heptanol. During 3-Hz pacing CM monolayers exhibited reentrant arrhythmias with greater induction rate in CM/MF models (67.4%, n=43) than that in the CM/CM models (22.2%, n=27, $p<0.01$). In contrast, high-K^+ (8mM) perfusion in the CM/CM models, which slowed CV (41.3±7.6mm/s) equivalent to that in the CM/MF models under control K^+ (4mM) perfusion, barely induced arrhythmias (10.0%, n=10). In confocal immunofluorescence analysis for connexin 43 (Cx43) plaques at the membrane pores, the CM/MF model revealed denser distribution (35.5±3.5%, n=6) in the reentrant cores than in the surroundings (24.6±5.0%, n=6, $p<0.01$), suggesting greater electrotonus of MFs to CMs on the core than the surroundings. However, the CM/CM models that failed to induce arrhythmia showed no regional difference in Cx43 density (n=6). **In conclusion**, heterocellular coupling of CM monolayer with MFs depresses CV, but spatial non-uniformity in the coupling is requisite for reentrant arrhythmogenesis.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Arterial hypertension promotes atrial remodelling and fibrillation in pigs

G. Antoons[1], M. Schwarzl[1], G. Jin[1], D. Zweiker[1], S. Huber[2], J. Verderber[1], A. Alogna[1], P. Schoenleitner[1], P. Wakula[1], A. Lueger[3], F.R. Heinzel[1], B. Pieske[1] and H. Post[1]

[1]Cardiology, Medical University Graz, Graz, Austria, [2]Cardiac Surgery, Medical University of Graz, Graz, Austria and [3]Internal Medicine, Medical University of Graz, Graz, Austria

Arterial hypertension is an independent risk factor for atrial fibrillation (AF). The occurrence of AF is related to atrial dilation and extracellular matrix remodelling, shortening of atrial refractory period (AERP), and disturbed Ca^{2+} handling. In this study, we investigate if chronic hypertension in a porcine model induces structural and electrical changes in the atria, including Ca^{2+} homeostasis, and whether these changes enhance susceptibility to AF.

To induce hypertension, 8 landrace pigs received subcutaneous DOCA-pellets (aldosterone analogon, 90-day release) and high-lipid/salt diet for 12 weeks. Eight weight-matched pigs served as controls. AERP was determined at different cycle lengths, S0, followed by a premature extrastimulus with 5 ms decrements. To test for AF susceptibility, a separate group of pigs (N=16) was instrumented with a telemetry-controlled pacemaker. Surgical procedures and in vivo interventions were performed under anesthesia (1.0 % isoflurane, 35 μg/kg/h fentanyl, 1 mg/kg/h midazolam, and 0.2 mg/kg/h pancouronium). A number of 5/16 pigs received DOCA/salt starting 2 weeks before the onset of rapid atrial pacing (600 bpm). After 2 weeks pacing, spontaneous atrial rhythm was monitored in unsedated pigs. AF susceptibility was defined as no detectable sinus rhythm for > 1h.

Atrial myocytes were isolated from 12 w-treated DOCA (N=3) and control pigs (N=4), from left (LA) or right atrium (RA). Calcium transients (CaT) and cell shortening were measured during field stimulation using Fura-2 AM (0.5 – 2 Hz, 37°C). Data are expressed as mean ± s.e.m.

After 12 w DOCA, systolic blood pressure was 139±11, vs 95±6 mmHg in control pigs ($P<0.05$, tail-cuff-method). LA area was enlarged (12.4±0.3 vs 9.7±0.6 cm^2 in control, $p<0.05$, echocardiography). Interstitial fibrosis was reduced (14.8±1.8 vs 20.5±1.7% in control, $p<0.05$, expressed as % stained area by Sirius Red). AERP was significantly shortened in DOCA (fig 1). In single atrial myocytes, CaT amplitude was comparable in DOCA and control, in LA and RA. In LA, but not in RA, diastolic Ca^{2+} levels were lower (0.54±0.02 $F_{340/380}$, n=5, N=1, vs 0.81±0.01 in control, n=7, N=2, 0.5 Hz), and Ca^{2+} decline was faster (RT_{50} 81±24 ms, vs 197±21 ms in control, 0.5 Hz). While unchanged in RA, in LA cells, cell shortening was increased from 2.3±0.8% in control (n=3, N=2) to 5.4±0.5% in DOCA (n=8, N=1, 0.5 Hz). DOCA pigs were more susceptible to AF. After 2 w of rapid pacing, sustained AF (>1h) occurred in 4/5 DOCA pigs, vs 2/11 control pigs ($p<0.05$).

In conclusion, although sinus rhythm is maintained, hypertensive pigs develop left atrial dilation and reduced electrical refractoriness, which was related to enhanced AF susceptibility. At the myocyte level, faster Ca^{2+} kinetics and increased contractility may reflect compensatory mechanisms that primarily occur in the left atria during chronic hypertension.

NADH and FAD kinetics reveal altered mitochondrial function in right ventricular heart failure

R.C. Wüst[1], M. Helmes[1,2] and G.J. Stienen[1]

[1]Department of Physiology, VU Medical Center, Amsterdam, Netherlands and [2]IonOptix llc, Milton, MA, USA

Purpose. In chronic heart failure, alterations occur in cardiac metabolism, enzyme content calcium handling and mitochondrial function. However, little is understood about the influence of alterations in mitochondrial function on energy metabolism during the transition from cardiac hypertrophy (CH) to failure (HF). A photometry-based technique (cf. 1) was used to simultaneously measure contractile function and autofluorescence of NADH (reduced nicotinamide adenine dinucleotide; electron donor to complex I) and FAD (oxidized flavin adenine dinucleotide; product after supplying electrons to complex II) in thin cardiac trabeculae.
Methods. Three groups (n=6 in each) were studied: CH (monocrotaline (MCT) injection s.c.: 40 mg.kg^{-1}) or HF (MCT: 60 mg.kg^{-1}) and CON (saline). After 23±1 days, hearts were dissected from isoflurane-anaesthetised male Wistar rats. Right ventricular trabeculae were excised, attached to a force transducer at optimal length and superfused with oxygenated tyrode with both 1 and 0.5 mM Ca^{2+}. Autofluorescence of both NADH (excitation: 340 nm; emission: 460 nm) and FAD (ex: 450 nm; em: 525 nm) were recorded using an inverted microscope during transitions in pacing frequency between 0.5 and 3 Hz at 27 °C.
Results. Upon an increase in pacing frequency from 0.5 to 3 Hz, force-time integral increased less in CH and HF compared to CON (4.0±1.4 and 3.2±0.2 vs. 5.6±1.4 fold, respectively). NADH autofluorescence dropped abruptly upon an increase in pacing frequency. Larger changes were observed in HF compared to CON, with CH showing intermediate responses. In CON, steady-state NADH concentration after 3 min of stimulation at 3 Hz was lower than steady state values at 0.5 Hz. In contrast, steady state NADH concentration was higher than at 0.5 Hz in CH and this increase was larger in HF. FAD responses showed a mirror image. The amplitudes of the responses of NADH and FAD were more pronounced in 1 mM compared to 0.5 mM Ca^{2+}.
Conclusions. Despite a smaller increase in the force-time-integral, the initial changes in NADH and FAD were more pronounced in CH and HF than in CON, indicating a larger deviation in metabolic homeostasis in CH and HF. Lower NADH and higher FAD throughout the 3 Hz contractions confirm net oxidation upon an increase in ATP demand in CON (1). In contrast, the higher steady-state NADH and lower FAD concentration in CH and HF point towards net NADH and $FADH_2$ production in CH, which is exacerbated in HF. These results are suggestive of a mismatch between dehydrogenase activity and oxidative phosphorylation, and reveal an altered mitochondrial function in CH and HF.

PCA034

Conduction of excitation in the rabbit and rat pulmonary veins myocardium under normal conditions and parasympathetic stimulation

V.S. Kuzmin, Y.V. Egorov and L.V. Rosenshtraukh

Laboratory of Heart Electrophysiology, Russian Cardiologic Research and Production Complex, Moscow, Russian Federation

Much attention is paid to the pulmonary veins (PVs) myocardium as a region responsible for atrial fibrillation (AF) triggering. It has been recognized re-entrant circuits and anisotropic conduction in the human PVs myocardial sleeves, that, probably, responsible for the onset of AF. However, the electrophysiologic properties of the PVs in laboratory animals have not been well characterized.
The aim of the present study is to investigate excitation wave conduction in rabbit and rat PVs myocardium with use of optical mapping technique.
Rabbits (male, 2.6-3.2 kg) and rats (male, 250-300 g) were anaesthetized with an urethane (1.5 g/kg i.v. and 2 g/kg i.p, respectively), preparations consisting of left atrium (LA) and PVs of left lung lobe were dissected. All procedures accorded with current Russian guidelines for the use of experimental animals.
Tyrode superfused isolated preparations were treated with potential sensitive dye di-4-ANEPPS (5 μM) in presence of 2,3-butanedione monoxime (1 g/l). Optical signals were captured with use of high speed CCD camera (WuTech Instruments). Cardioplex software (RedShirtImaging) was applied for conduction velocity and action potentials duration (APDs) estimation, isochronic maps reconstruction.
Rabbit PVs characterized by a very short zone (2-3 mm), which conduct excitation and by an abrupt transition to unexcitable nonmyocardial regions. Maximal conduction velocity (θ) in the conducting zone of rabbit PVs does not demonstrate significant difference with LA (65±7 and 69±6 cm/s, respectively, n=8, P>0.1). Also, no differences were seen for wavelength (55±6 and 58±6 mm, n=8) estimated with use of APDs. No conduction slowing, disturbances or blocks were observed in rabbit PVs at various patterns of stimulation or acetylcholine (ACh) application (5 μM).
Conduction of excitation was observed in distal and even intrapulmonary regions of rats PVs. Rat LA and PV myocardium also demonstrated weak differences in the conduction velocity.

Maximal θ in LA - 84 ± 14 cm/s, the same parameter in PVs was 71 ± 11 cm/s (n=12, P>0.1). Wavelength for rat LA - 37 ± 5, and for PVs 43 ± 7 mm (n=12, P>0.05).
Regions, that characterized by conduction slowing and blocks, were shown in rat PVs, but not in LA myocardium. Marked decreasing of conduction velocity and inexcitability were demonstrated in the rat PVs after periods (5 min) of quiescence (absence of stimulation). Application of ACh (5 μM, n=6) restore excitability and conduction velocity to the normal level. These data suggest functional similarity LA and PVs myocardium and PVs nonsusceptibility to conduction abnormalities in rabbits in contrast to rats. Significant distinction of conduction in PVs may be critical to experimental data interpretation in AF investigation.

PCA035

Chaotic excitation spread during tachycardia-like excitation in the rat isolated atrium revealed by optical mapping studies

T. Sakai[1] and K. Kamino[2]

[1]Department of Systems Physiology, Graduate School and Faculty of Medicine, University of the Ryukyus, Nishihara, Japan and [2]Tokyo Medical and Dental University, Tokyo, Japan

We have been carrying out experiments that involve the mapping of excitation spread in the isolated rat atrial preparation using multiple-site optical recording methods [1, 2]. When the tetanus stimulation was applied to the preparation, long-lasting rhythmical excitation with high frequency, which looks like tachycardia, occurred. We call this phenomenon as "tachycardia-like excitation" [3 - 5]. We found the chaotic excitation spread during this event. Adult rats were anesthetized by inhalation of ether, and the hearts were removed quickly. The isolated atrial preparations were stained with a fast voltage-sensitive merocyanine-rhodanine dye (NK2761). The preparation chamber was mounted on the stage of a microscope equipped with 16 X 16 or 12 X 12 -element photodiode array. Optical action potentials were recorded from 256 or 144 adjacent areas of the preparation simultaneously. Then, maps of excitation spread were made. From the spatio-temporal patterns of excitation spread on the map, the characteristics of "tachycardia-like excitation" are summarized as follows.

1. Tachycardia-like excitation is the generation of (or "transition to") a new pattern of excitation spread evoked by perturbing the "normal" pattern.
2. During its generation, transitional unstable complex (so called "chaotic") patterns of excitation spread, with blocked areas and ectopic foci, are observed.
3. After this phase, a new quasi-stable pattern appears. It is "quasi-stable" because the newly emerged pattern often returns to the original "normal" pattern spontaneously.
4. Event-to-event variations are always observed. Furthermore, preparation-to-preparation variations are also observed. During the event of tachycardia-like excitation, cycle-to-cycle variations (for circus movement) and/or site-to-site variations (for ectopic focus, i.e. spatial sift of the focus) are also observed. Based on the evidences shown above, we consider that tachycardia-like excitation is an example of a functional "self organizing system", although the physiological background is still unclear. Especially, the event-to-event variations seem to result from physiologically trivial difference(s) of the initial conditions. This characteristic of a "complex system" strongly supports this idea. We consider the quasi-stable state observed here as the "physiology-specific attractor". This study was carried out in accordance with Act on Welfare and Management of Animals of Japan, and approved by the Animal Care and Use Committee, Tokyo Medical and Dental University.

PCA036

Early growth response 1 acts as an early signal to induce Cav3.2 T-type calcium channels during cardiac hypertrophy in mice

S. Hsu[1,2] and C. Chen[1]

[1]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taipei, Taiwan and [2]Institute of Biochemistry and Molecular Biology, National Yang-Ming Univ, Taipei, Taiwan

Voltage-gated T-type Ca2+ channels (T-channels) are highly expressed in embryonic but undetectable in adult ventricular myocytes. Interestingly, T-channels are reexpressed in hypertrophied or failing hearts. It has been shown that Cav3.2 T-channel is involved in the pathogenesis of cardiac hypertrophy via the activation of calcineurin/nuclear factor of activated T cells (NFAT) pathway (Chiang et al, 2009). However, it is unclear when and how Cav3.2 is induced during cardiac hypertrophy. Because the mRNA re-expression is mainly through the transcriptional regulation in the promoter or enhancer conserved in different species, we hypothesized that the evolutionary conserved promoter (ECP) of Cav3.2 carries important binding sites for transcription factors that regulate its re-expression in the hypertrophic hearts. In this study, we obtained the ECP of Cav3.2 by aligning Cav3.2 genes from different species. By fusing mouse ECP with the reporter gene firefly luciferase, we showed that the ECP drove high luciferase activity in the cells expressing endogenous Cav3.2 but not in the one without Cav3.2. To further validate ECP in vivo, we generated transgenic mice expressing luciferase reporter driven by Cav3.2 ECP (Tg-Cav3.2-Luc). Analysis of the Tg-Cav3.2-Luc

mice showed that ECP confers the reporter expression similar to the endogenous Cav3.2 in the tissue distribution, development of hearts, and most importantly, the inducibility of hypertrophic stimulation. The left ventricular luciferase activity can be induced as early as 3 days after pressure overload created by trans-aortic banding (TAB) surgery (Chiang et al, 2009). By injecting reporters driven by different truncated promoters followed by TAB surgery, the hypertrophic regulatory element was located within -420 bp relative to the transcription start site (TSS) of Cav3.2. We searched the putative TF binding sites within the proximal 420 bp of mouse Cav3.2 5'-flanking sequence (Cav3.2-420) using the TFSEARCH and confirmed that early growth response 1 (Egr1) is the important transcription factor to enhance Cav3.2 gene expression. We showed the Egr1 could bind to the -81 to -41 bp upstream of Cav3.2 TSS using MESA and Chip assays. The protein level of Egr1 in left ventricle was also upregulated at 3 days after TAB, the same time point when the Cav3.2-Luc was induced in Tg-Cav3.2-Luc. To demonstrate that Egr1 indeed regulates Cav3.2 expression after hypertrophic stimulation, we showed that knockdown of Egr1 using siRNA prevented the phenylephrine (PE)–induced upregulation of Egr1, Cav3.2 and cellular hypertrophy in H9C2 cells. Furthermore, overexpression of Cav3.2 in Egr1 knockdown cells restored the PE-induced hypertrophy. In conclusion, our results demonstrate that Egr1 regulates the expression of Cav3.2 T-type calcium channel in cardiac hypertrophy.

PCA037

Modulation of Ca^{2+} uptake by changing of SERCA activity in mouse myocardium did not alter Ca^{2+} leak from sarcoplasmic reticulum in physiological condition

S. Morimoto[1], K. Hongo[1], M. Kawai[1], J. O-Uchi[3], Y. Kusakari[2], K. Komukai[1], M. Yoshimura[1] and S. Kurihara[2]

[1]Division of Cardiology, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan, [2]Department of Cell Physiology, The Jikei University School of Medicine, Tokyo, Japan and [3]Department of Medicine, Thomas Jefferson University, Philadelphia, PA, USA

Introduction Intracellular Ca^{2+} handling in cardiac muscle plays an important role in cardiac contraction and relaxation. Recently, increased Ca^{2+} leak from sarcoplasmic reticulum (SR) through ryanodine receptor has been reported to decrease cardiac contraction. It has been also reported that there were more heart failure patients with preserved cardiac contractility than we expected in clinical field. Heart failure with preserved contractility presents diastolic dysfunction, which may be caused by impaired relaxation due to decreased Ca^{2+} uptake into SR. However, the relationship between Ca^{2+} uptake and leak in SR has not been fully investigated. In the present study, we investigated the relationship between Ca^{2+} leak from SR through ryanodine receptor and Ca^{2+} uptake into SR by SR Ca^{2+}-ATPase (SERCA). **Methods** We used the mice hearts with overexpression of SERCA (SERCA-TG) or sarcolipin (SLN-TG) which suppresses SERCA activity. The hearts were quickly removed from mice anesthetized with sodium pentobarbital (300 mg/kg intraperitoneal administration). We used saponin-treated thin trabeculae and papillary muscles obtained from these mice hearts. Each SR function of these mice hearts was estimated by measuring the Ca^{2+} content in SR by using caffeine (50 mM) and fluo-3 when SR was loaded in the solution with various Ca^{2+} concentrations (pCa 8-5.6) and loading time (10-300 sec). Ca^{2+} transient and tension in twitch contraction of intact papillary muscles from mice were also measured. To estimate the effect of the beta-adrenergic stimulation on myocardium in SERCA-TG and SLN-TG, isoproterenol (100 nM) was applied to papillary muscles obtained from mice hearts. **Results** At short Ca^{2+} loading time, Ca^{2+} content in SR was larger in SERCA-TG (159%) and smaller in SLN-TG (50%) compared to each control myocardium. Ca^{2+} leak from SR in SERCA-TG and SLN-TG did not differ from each NTG. In SERCA-TG heart, the peak of Ca^{2+} transient increased and the time course of Ca^{2+} transient was accelerated. In SLN-TG heart, the peak of Ca^{2+} transient decreased and the time course of Ca^{2+} transient was slowed. In the papillary muscle preparation from control, isoproterenol increased Ca^{2+} transient and tension and accelerated time courses of both signals. In the papillary muscle preparation from SERCA-TG, Ca^{2+} transient and tension were not increased and time courses of both signals were not altered by isoproterenol treatment. In papillary muscles preparation from SLN-TG, Ca^{2+} transient and tension were significantly increased and time courses of both signals were significantly altered by isoproterenol treatment (e. g. Asahi *et al*. (2004)). **Conclusion** Selective modulation of Ca^{2+} uptake into SR influenced time course of Ca^{2+} transient, however, it did not influence Ca^{2+} leak from SR.

PCA038

The Langendorff perfused heart and cardiac tissue slices, a comparison study

K. Wang[1], P. Lee[2], D. Gavaghan[1], P. Kohl[1,3] and C. Bollensdorff[3,4]

[1]Department of Computer Science, Oxford University, Oxford, UK, [2]Physics Department, Oxford University, Oxford, UK, [3]Heart Science Center, Imperial College London, London, UK and [4]Qatar Cardiovascular Research Center, Doha, Qatar

Several studies have shown that cardiac tissue slices are a good candidate for drug testing [1-4]. Furthermore cardiac slices as pseudo 2D preparations of heart muscle are a good experimental model to study patho-physiological mechanisms. However, similarities and differences of cardiac slices as compared to whole heart electrophysiological parameters have not yet been investigated in detail. We established a new method to compare action potential (AP) properties of intact whole-heart and cardiac tissue slices from the same heart.

Whole Langendorff-perfused hearts from female guinea pigs (300-400g) were bolus loaded with di-4-ANBDQPQ (15μL, 19mg/mL Ethanol). For AP mapping an EMCCD camera (~500fps) was used. A blue LED (CBT90, Luminus) was used [5] to minimize penetration depth, while being efficient to evoke a sufficiently strong signal, weighted towards the subsurface of the left ventricle (LV). The hearts were perfused with modified Krebs buffer containing 10μM blebbistatin. The solution was bubbled with carbogen and recirculated (8mL/min). The heart was held in a mould and the perfusion cannula was fixed to the specimen holder of a microtome. For whole heart

stimulation two platinum electrodes where placed about 0.5 cm away from the heart (40V, 2 to 5ms, bipolar) in the bath surrounding the tissue. Several cardiac tissue slices (400μm) were cut tangentially to the LV surface (microtome 7000smz, advance speed 0.02mm/s, blade frequency 80Hz). While the whole heart was imaged in the bath before each section, the cardiac slices were transferred to a special slice imaging station. The bath temperature in both set ups was kept at 35±2oC. The solution of the slice bath was also bubbled with carbogen between measurements, and continuously circulated for additional bubbling.

Living tissue slices could successfully obtained from the Langendorff heart, perfused at body temperature, avoiding the need to section from tissue wedges in ice-cold solution. Tissue slices differ from LV tissue in many ways, including mechanical load, electrical source-sink relations, and activation pathways. Slices do deform after sectioning, due to the lack of mechanical strain from neighbouring tissue. Therefore the exact AP pattern in a slice is different from a corresponding tissue area in whole heart. However, slices preserve several key characteristics of the AP, such as overall APD distribution, AP shape, and response to variation in stimulation rate. Therefore, within limits, cardiac tissue slices may be a useful model for exploration of cardiac electrophysiology in relation to identifiable underlying tissue sources, and may be particularly useful for differential studies involving before/after investigations, such as for the study of drug effects.

Low Na increases ventricular gap junction resistivity and phosphorylation levels of connexion43-serine 368: Possible synergistic interaction between calcineurin and protein kinase C

A. Waheed, S.C. Salvage, A. Orlowski, C.C. Fry and R.I. Jabr

Biochemistry and Physiology, University of Surrey, Surrey, UK

Ventricular arrhythmias are initiated by abnormal action potential (AP) conduction partially caused by an increased gap junction (GJ) resistivity (R_j). Alterations in ventricular GJ electrical properties may result from either raised $[Ca^{2+}]_i$ and/or changes in the phosphorylation state of GJ proteins, connexin 43 (Cx43). In particular, the phosphorylation of the serine residue at 368 site (Cx43-pS368) by protein kinase C (PKC). We have reported that the slowed AP conduction velocity induced by raised $[Ca^{2+}]_i$ was reversed by cyclosporin A (CsA), an inhibitor of the Ca^{2+}/calmodulin serine-threonine dependent protein phosphatase, calcineurin (Cn). In this study we tested the hypothesis that raised $[Ca^{2+}]_i$ increases R_j as a result of increased Cx43-pS368 levels caused by a possible interaction between Cn and PKC.

Guinea-pig left ventricular papillary muscles were dissected in Tyrode's solution (total [Na]=147.4mM; 24mM $NaHCO_3$, 5%CO_2, 37°C). Tissue impedance (Z) was measured over a range of frequencies (0.02-100kHz) using the oil gap technique. R_j was calculated from Z values in control and low Na Tyrode's solutions (29.4 mM Na, used to increase $[Ca^{2+}]_i$) in the absence/presence of Cn inhibitors (CsA, 5μM and Cn-autoinhibitory peptide,CAIP, 50μM) or PKC inhibitor (chelerythrine, CHE, 2μM). The protein expression of total Cx43 (T-Cx43) as well as Cx43-pS368 was determined from whole tissue lysates using western blotting. Cx43- pS368 bands were in turn normalised to their corresponding T-Cx43 (Cx43-pS368/T-Cx43). Data are means ± SEM, compared by ANOVA, the null hypothesis rejected at $p<0.05$.

R_j was significantly increased by low Na (608 ± 104Ω.cm) when compared to control (403 ± 62Ω.cm; n=7; $p<0.001$). Such an effect was reversed by CsA (475±100 Ω.cm; n=7;$p<0.001$) which alone had no effect. Similar effects were observed with CAIP. Combination of low Na and CHE partially inhibited the rise in R_j induced by low Na alone (control:232.5Ω.cm; low Na:397.5Ω.cm; low Na and CHE: 316.6 Ω.cm; n=2). Moreover, T-Cx43 protein expression was unchanged during all interventions when compared with control. However, there was a significant increase of the Cx43-pS368/T-Cx43 in low Na (0.90±0.64; n=6; $p< 0.05$) when compared to control (0.05±0.02;n=6). Such an increase was reversed by CsA (0.15±0.04; n=6; $p<0.001$) or CHE (0.03±0.01; n=3; $p<0.001$) in the presence of low Na solution.

Raised $[Ca^{2+}]_i$ in ventricular myocardium is associated with CsA and CHE-sensitive increase in R_j caused by increased Cx43-pS368 protein levels. This site is known to be targeted by PKC and lowering Cx43 gap junction conductance. In conclusion, we propose a possible synergistic interaction between Cn and PKC evoked by raised $[Ca^{2+}]_i$ slowing AP conduction a mechanism known to be proarrhythmogenic.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Exercise training in doxorubicin induced cardiomyopathy

C. Matsuura[1], C. Peres[1], E.M. Carvalho[1], V.N. Rocha[1], J.J. Carvalho[2], A. Mendes-Ribeiro[1,3] and T.M. Brunini[1]

[1]Pharmacology, State University of Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil, [2]Histology and Embriology, State University of Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil and [3]Physiological Sciences, Federal University of the State of Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil

Introduction One of the most serious adverse effects of doxorubicin (DOX) chemotherapy is the development of cardiomyopathy. Here we sought to investigate whether exercise

training would ameliorate structural cardiac damage after the development of DOX-induced cardiomyopathy.
Methods 48 male Sprague Dawley rats (220-250 g) received intraperitoneal injections of DOX (1 mg.kg-1.day-1, total 10 mg.kg-1) or 0.9% saline (SAL). Four weeks after injections, they were further divided into exercise (EX) or sedentary (SED) groups. EX groups exercised on a treadmill (30 min.d-1, at 60% of maximal velocity, 5 d.wk-1, for 6 wk). Forty eight hours after the last exercise bout, rats were anesthetized with thiopental (50 mg.kg-1, i.p.), and the heart was removed after KCl intracardiac injection. Fragments of the left ventricle were fixed at 2.5% glutaraldehyde in a 0.1 M cacodylate buffer and post-fixed in 1% osmium tetroxide with 0.8% potassium. Thereafter, fragments were dehydrated in acetone and embedded in Epon. Semithin sections were cut and stained with toluidine blue and observed with a light microscope. Ultrathin sections were obtained from selected areas with ultramicrotome, counterstained with uranyl acetate and lead citrate, and examined with a Zeiss EM 906 transmission electron microscope at 80 Kv. All experimental procedures were approved by the Institutional Animal Care and Use Committee (CEA/051/2009).
Results Before starting training, cardiac dysfunction was confirmed by echocardiography in DOX rats, which showed significant reduction of 24 ± 4% in shortening fraction, and enlarged end-diastolic and end-systolic diameters. An elevated mortality rate was observed in both DOX/groups, but it was significantly lower in DOX/EX (33%) than in DOX/SED (67%) assessed by log rank test (P<.05). Ultrastructural analysis of the heart showed myocardial damage in both DOX/SED and DOX/EX (Fig.1C and 1D) when compared to the SAL/SED and SAL/EX groups (Fig. 1A and 1B). These changes consisted of mitochondria damage with degeneration or loss of cristae and intramitochondrial vacuoles. Moreover, we observed an increase in the mitochondrial matrix caused by mitochondrial loss and intense disarray and fragmentation of myofilaments.
Fig.1. Electron micrographs of cardiac specimens. A, saline/sedentary; B, saline/exercised; C, doxorubicin/sedentary; D, doxorubicin/exercise. Bars 2 μm.
Conclusion The increased survival observed in the DOX/EX group cannot be attributed to an improved myocardial structure. We had previously reported that exercise training led to an improvement in vascular smooth muscle relaxation,1 and therefore we believe that despite the absence of changes in the heart structure, the reduced afterload could contribute to a reduced myocardial oxygen demand.

The effect of Mudanpi and its main active component on cardiac ischemia and ion channels

Y. Ma, P.J. Noble, S. Lee, R. Wilkins, C. Ellory and D. Noble

Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK

Mudanpi, a herbal medicine prepared from the root bark of Paeonia Suffruticosa, was traditionally used for thousands of years to 'remove pathogenic heat from blood'. Previous studies showed that Mudanpi has a significant cardioprotective effect against cardiac ischemia (Ma et al 1984), and its active component, paeonol, inhibits the pacemaker potential of cultured myocytes (Ma et al 1986) suggesting that paeonol might influence the activity of cardiac ion channels. Further studies indeed showed that paeonol has a significant effect on the ion channels of cardiac myocytes (Ma et al 2006). We present here the findings obtained over many years from the East to the West; data were collected from heart ischemic model to ion channel activities of the isolated cardiac myocytes using patch clamp electrophysiological method.
The cardiac ischemic model was established by coronary artery occlusion in canines; extract of mudanpi was infused intravenously. The epicardial ECG were recorded by applying 30 electrodes to predetermined epicardial sites. The electrodes were connected to an amplifier, and the epicardial ECG recorded. The elevation of S-T segments were used as a measure of the degree of ischemia. Aterial pressure, heart rate and heart oxygen consumption were recorded. The actions of paeonol on ionic channel were studied using the standard whole-cell configuration of the patch-clamp technique in isolated guinea-pig ventricular myocytes. The effects of paeonol on the action potential (AP) and a variety of ion channels were studied, and the possible mechanisms underlying the alteration of ion channel function were analysed.
The results showed that Mudanpi had a significant protective effect against acute ischemic injury by reducing myocardial oxgen comsumption, reducing cardiac arrhythmic risk, lowering blood pressure and heart rate. The main effect of paeonol on the ventricular myocytes was to shorten the AP duration, suppress the AP upstroke velocity and amplitude, actions associated with the blockade of the voltage-gated, fast sodium current. The shortening effect of paeonol on the AP duration was independent of the blockade of the fast sodium current, and the blockage of calcium current, nor did it activate ATP-sensitive potassium current or chloride current. However, paeonol did block the slowly inactivating sodium current, and blockade of this current is known to result in AP shortening. Using the Noble Heart computational model (Noble et al 1998) we predicted that paeonol inhibits ADP of the AP, a strong indication of antiarrythmic action.
These findings suggest that paeonol, and therefore Mudanpi, may possess antiarrhythmic activity, which may confer their cardioprotective effects.

Opioid receptors involved in cardioprotection of chronic intermittent hypobaric hypoxia in rats through a PKC/ERS signaling pathway

Y. Zhang[1], F. Yuan[1], L. Zhang[2] and S. Wang[1]

[1]Hebei Medical University, Shijiazhuang, China and [2]The third Hospital, Hebei Medical University, Shijiazhuang, China

Background: Chronic intermittent hypobaric hypoxia (CIHH) protects myocardium against ischemia/reperfusion injury. This study aimed to investigate whether opioid receptors participate in cardioprotection of CIHH rats for the first time.
Methods: Adult male Sprague-Dawley (SD) rats were exposed to hypoxia(simulated 5000m altitude)for 28 days, 6 hours per day. The hearts were subjected to 30 min ischemia and 60 min ensuing reperfusion using Langendorff technique. Cardiac function, infarct size, and active of lactate dehydrogenase (LDH) were measured. Expression of opioid receptors and endoplasmic reticulum stress (ERS) molecular chaperones (GRP78, CHOP and caspase-12) was revealed by Western blot analysis.
Results: In CIHH rats after I/R, the recovery of left ventricular function was improved, infarct size and activity of LDH was decreased, expression of and κ opioid receptors was up-regulated, and over-expression of GRP78, CHOP and caspase-12 was inhibited (P< 0.05). All above-mentioned effects of CIHH were abolished respectively by the nonselective opioid receptor antagonist Naloxone, the selective κ-opioid receptor antagonist BNI and the selective δ-opioid receptor antagonist NTI.However,the nonselective opioid receptor agonist morphine, the selective κ-opioid receptor agonist U50488H, and the selective δ-opioid receptor agonist DADLE exerted a protective effect on heart against I/R, and decreased over-expression of GRP78, CHOP and caspase-12 in I/R myocardium of control rats (P<0.05).The cardioprotection of CIHH and opioid agonists was inhibited by CHE, a PKC blocker. The inhibitory effects of CIHH on ERS were also blocked by CHE.
Conclusions: CIHH protects heart against I/R injury through activating opioid receptors and via a PKC/ERS pathway in rats.

Post-transcriptional regulation of human ether-a-go-go-related gene potassium channel protein by AT1 receptor stimulation

Y. Cai, Y. Wang, X. Zuo and Y. Xu

Hebei Medical University, Shijiazhuang, China

There is increasing evidence that angiotensin II (Ang II) is associated with the cardiac electrical remodeling and thus the occurrence of ventricular arrhythmias under pathological conditions. Human ether-a-go-go-related gene (hERG) encodes the pore forming subunit of the channel underlying IKr, which is crucial for the repolarisation of cardiac action potentials. Our previous study has shown that Ang II produces an acute inhibitory effect on IKr/hERG currents via AT1 receptors in guinea pig ventricular myocytes. The present study was designed to investigate the post-transcription regulation of hERG channel protein by chronic stimulation of AT1 receptors in heterologous expression system. An HEK 293 cell line stably expressing hERG channels was established and human AT1 receptor was transiently co-transfected. Western-blot analysis showed that Ang II decreased the abundance of mature hERG protein (155-kDa) in a time- and dose-dependent manner without affecting the level of immature hERG protein (135-kDa). The relative intensity of mature 155-kDa band as control was 68 ± 4% after incubation of Ang II at 100 nM for 24 hours (P<0.01, n=6). Values are means ± S.E.M. of n experiments, compared by two-tailed Student's t test. To investigate the effects of Ang II on degradation of mature hERG channels, we blocked forward trafficking with a Golgi transit inhibitor brefeldin A (BFA, 10 μM). Ang II significantly enhanced the time-dependent reduction of mature hERG channels. A proteasomal inhibitor lactacystin (5 μM) significantly inhibited Ang II-mediated reduction of the mature protein (from 67 ± 4% to 89 ± 3%, P<0.05, n=3), but the lysosomal inhibitor bafilomycin A1(1 μM) had no significant effect on the role of Ang II. It indicated that Ang II accelerated channel protein degradation, primarily through the proteasome pathway. The protein kinase C inhibitor bisindolylmaleimide I antagonized the reduction of mature 155-kDa proteins by Ang II, suggesting that the effect of Ang II was mediated by intracellular PKC signaling pathway. In conclusion, the chronic incubation of Ang II reduced the mature hERG channel protein by accelerating channel degradation through a PKC pathway. The findings suggest a potential mechanism by which elevated levels of Ang II may be involved in the hERG channel remodeling in heart diseases.

Pharmacological and pH modulation of sodium-dependent background current in rabbit atrioventricular node cells

H. Cheng[1], M.R. Boyett[2], C.H. Orchard[1] and H.C. Jules[1]

[1]School of Physiology and Pharmacology, University of Bristol, Bristol, UK and [2]Institute of Cardiovascular Sciences, University of Manchester, Manchester, UK

The atrioventricular node (AVN) plays a critical role in normal cardiac conduction and can also take over pacemaking of the ventricles should the sinoatrial node fail. The cellular electrophysiological basis of AVN pacemaking is incompletely understood, although it is likely to involve multiple ionic conductances (Inada *et al*., 2009). The potential importance of a background inward conductance in sinoatrial node cells has long been recognised (Hagiwara *et al*., 1992), and we recently presented preliminary evidence for a sodium-dependent background current ($I_{B,Na}$) in rabbit AVN cells (Cheng *et al*., 2012). The present study was designed to investigate further the characteristics of $I_{B,Na}$ from rabbit AVN cells. Adult male New Zealand White rabbits were killed in accordance with UK Home Office legislation and AVN cells were isolated as described previously (Cheng *et al*., 2009). Whole-cell voltage-clamp using voltage-ramp protocols was used to record the background current, after the Ca^{2+}, K^+, Na^+-K^+ pump and Na^+-Ca^{2+} exchange (NCX) currents were inhibited by appropriate blockers (Hagiwara *et al*., 1992). Values are means±SEM, compared by ANOVA or *t*-test. Since $I_{B,Na}$ is Na^+-dependent, in order to preclude the involvement of NCX current (I_{NCX}), Ni^{2+} was applied at a concentration (10 mM) which produces profound block of I_{NCX} (Hinde *et al*., 1999). 10 mM Ni^{2+} caused only a small decrease in the amplitude of $I_{B,Na}$ at -100 mV, from -1.27±0.11 pA/pF (in 2 mM Ni^{2+}, which was present in all solutions and substantially inhibits the NCX; Hagiwara *et al*, 1992; Hinde *et al*, 1999) to -0.98±0.06 pA/pF (P<0.05, n=6 and7). $I_{B,Na}$ also persisted following application of a second NCX inhibitor (KB-R7943; 5 μM). These data demonstrate that $I_{B,Na}$ in rabbit AVN cells cannot be attributed to I_{NCX}. Amiloride (1 mM), which was reported to produce partial inhibition of $I_{B,Na}$ in sinoatrial node cells (Hagiwara *et al*., 1992), produced a modest reduction in $I_{B,Na}$ (-0.91±0.11 vs. -1.52±0.13 pA/pF in control at -100 mV, P<0.01, n=8). In contrast, changing extracellular solution pH from 7.4 to 6.3 markedly decreased $I_{B,Na}$ (to -0.43±0.08 pA/pF from -1.11±0.12 pA/pF at -100 mV, P<0.01, n=12). The sensitivity of $I_{B,Na}$ to extracellular acidosis is consistent with the notion that modulation of $I_{B,Na}$ is likely to contribute to previously reported effects of pH on AVN cell electrophysiology (Cheng *et al*., 2009).

PCA046

Investigation of the influence of hERG 1b on hERG channel pharmacology

A. EL Harchi[1], D. Melgari[1], H. Zhang[2] and J.C. Hancox[1]

[1]School of Physiology and Pharmacology, University of Bristol, Bristol, UK and [2]School of Physics and Astronomy, The University of Manchester, Manchester, UK

hERG channels mediating the rapid delayed rectifier K^+ current (I_{Kr}) are important for normal ventricular repolarisation. In native cardiac tissues, the hERG 1a subunit co-assembles with a subunit encoded by an alternate transcript, "ERG1b" which has a shorter N-terminus and influences current kinetics (Jones et al, 2004). There is some evidence that hERG 1b may confer altered pharmacological properties on hERG 1a/1b compared to hERG 1a alone (Sale et al, 2008; Abi-Gerges et al, 2011). Some of this evidence derives from automated patch-clamp at room temperature (RT). As hERG kinetics show a complex temperature dependence (Vandenberg et al, 2006), we have sought to investigate comparative pharmacology of hERG 1a and hERG 1a/1b using manual patch clamp at physiological temperature and for some drugs at room temperature. HEK-293 cells stably expressing either hERG 1a alone or transiently co-transfected with hERG 1a and hERG 1b plasmid constructs were utilised. Effects of chloroquine and fluoxetine on hERG tail currents recorded at -40 mV (I_{hERG}) carried either by hERG 1a or hERG 1a+1b were assessed using a standard voltage clamp protocol (every 12s a 2-s depolarising step to +20mV followed by a repolarising step to -40mV to elicit tail currents were applied). Most experiments were performed at 37ºC; for fluoxetine (previously reported to be more potent against hERG 1a/1b than hERG 1a with automated patch clamp at room temperature (RT) (Abi-Gerges et al, 2011)), we compared RT and 37ºC. For concentration–response relations for drug inhibition of I_{hERG} tail at – 40 mV, four different concentrations of chloroquine and fluoxetine were tested (n=4 to 7 cells per concentration). We also examined the effect of a single concentration close to IC_{50} value for hERG 1a inhibiton by fluoxetine on I_{hERG}1a and I_{hERG}1a/1b elicited with a ventricular action potential voltage command at 37ºC. At 37ºC the sensitivity of I_{hERG} tails to each of chloroquine and fluoxetine did not differ between I_{hERG}1a and I_{hERG}1a/1b. At 25ºC the deactivation kinetics of both I_{hERG}1a and I_{hERG}1a/1b were slowed compared to 37ºC. This was accompanied by a ~2.1 fold decrease in sensitivity to fluoxetine for I_{hERG}1a/1b tails versus ~1.4 for I_{hERG}1a tails at 25ºC compared to 37ºC. We also observed a marked temperature dependence of the time-course of I_{hERG}1a inhibition by fluoxetine but this was not the case for I_{hERG}1a/1b. Finally, we did not observe any difference in I_{hERG}1a and I_{hERG}1a /1b sensitivity to 1 μM fluoxetine at 37ºC under AP clamp. Our

data are consistent with modest differences between I_{hERG}1a and I_{hERG}1a/1b pharmacology. These differences vary between drugs and experimental temperatures.

PCA047

Detecting diffusion barriers in rat cardiomyocytes with extended raster image correlation spectroscopy

P. Simson, N. Jepihhina, P. Peterson and M. Vendelin

Laboratory of Systems Biology, Institute of Cybernetics, Tallinn University of Technology, Tallinn, Estonia

A series of kinetic experiments show the existence of considerable ADP and ATP diffusion restrictions in rat cardiomyocytes (1,2). As an alternative method to estimate diffusion, we have extended raster image correlation spectroscopy — RICS (3) — - to study diffusion in anisotropic media, such as heart muscle cells (4). On the basis of the measurements on two different dyes, our analysis suggests that the diffusion restrictions are localized in certain areas of the cell (5). However, their location, physiological role, and the intracellular structures responsible for these restrictions are still unclear. We hypothesize that diffusion restrictions in cardiomyocyte are in the form of membrane-like barriers, and present a theoretical foundation for the use of RICS to determine the presence and the locations of such barriers. With a Gaussian point spread function of the microscope, the pair correlation function (PCF) for an impermeable membrane is calculated analytically, thus giving a convenient theoretical basis for the interpretation of microscopy data. We demonstrate that, in the proximity of the membrane, the PCF is not symmetric, as opposed to the case of homogeneous media. As a result, this property of PCF can be used to detect barriers. Indeed, our preliminary experimental results support this theory. We recorded fluctuations in fluorescence within the permeabilized rat cardiomyocyte along a line that was partially in the cell and partially in the solution. Paired-correlation RICS analysis shows that in the cell region the symmetry of the correlation function is modulated, but not in the solution. These results can be interpreted as an evidence that periodic diffusion barriers exists in rat cardiomyocytes.

Assay of the perfused rat heart during cardiac ischemia with Rb Electron Probe Microanalysis

V. Pogorelova and A. Pogorelov

Institute of Theoretical and Experimental Biophysics RAS, Pushchino, Russian Federation

Cardiac ischemia is followed by the potassium deficiency in cardiomyocyte [1-2]. The intracellular potassium concentration is an integrative result of active influx through Na^+/K^+-ATPase and passive transport via K^+ channels and anti- and symporters. Therefore the intensive potassium release may mask the pump activity. As Rb^+ is assumed to be a biological congener of K^+, and extracellular medium is modified to contain rubidium ions, ^{87}Rb NMR have been developed to mark K^+ fluxes between extracellular space and tissue [3]. Electron Probe Microanalysis (EPMA) allows the determination of elemental contents in cellular cytoplasm and this was utilized for Rb analysis in the neural and cardiac cells [4-5]. We applied EPMA to compare the kinetic parameters of potassium influxes at normoxic and ischemic conditions.

After decapitation the heart from 300-350 g male Wistar rat was perfused in the Langendorff mode with Tyrode's solution at a constant pressure of 70 mm Hg and the myocardial temperature was maintained at 38°C. Normoxic conditions were created with 95% O_2 + 5% CO_2 aeration of Tyrode. Ischemia was employed using glucose free solution equilibrated with 100% argon. Following 6 minutes of equilibration, hearts were perfused 5 min, 30 min, 45 min and 60 min at normoxic or ischemic conditions. Then papillary muscles were excised from the heart for EPMA technique [1]. Freshly isolated papillary muscle was frozen immediately by plunging into liquid propane (90°K) and cut in cryostat (240°K). Tissue cryosections were picked up and freeze-dried for 12 hours in a high vacuum. Freeze-dried cryosections were mounted on aluminium grids and intracellular rubidium content was examined in a scanning electron microscope JEOL JSM-U3 equipped with wavelength dispersive spectrometers. The section was viewed in the STEM mode at an accelerating voltage of 25 kV, a beam current of 1-5 nA and a probe diameter about 0.1 μm. EPMA data obtained are summarised in Table 1.

Experimental data of Rb EPMA allowed us to estimate the kinetic parameters [5]. Thus EPMA provides a method of determining uni-directional K fluxes in the cardiac myocell of perfused rat heart.

Table1. Changes of rubidium concentration (mM) in myocells of isolated rat heart during normoxic and ischemic Langendorff's perfusion with solution containing 2,5 mM Rb^+ and 2,5 mM K^+ *

Time of perfusion	Normoxic perfusion	Ischaemic perfusion
15 min	33±2	11±1
30 min	59±3	20±1
45 min	66±3	23±1

* EPMA data are presented as means ± S.E.M. for 100 myocells from 4 animals

HIP-55 inhibits isoproterenol-induced cardiac remodeling through negatively regulating p38 MAPK

Z. Li

Institute of Vascular Medicine, Peking University Third Hospital, Beijing, China and Key Laboratory of Cardiovascular Molecular Biology and Regulatory Peptides, Ministry of Health, Beijing, China

Cardiac remodeling is a common pathophysiological process shared by many cardiovascular diseases and is crucial in the transition of cardiac function from compensated to decompensated stage. It is closely related to the occurrence, development and prognosis of these diseases. The excessive activation of sympathoadrenal system(especially activation of β-ARs) is an important cause of cardiac remodeling and heart failure,while β-ARs blockers can observably improve the prognosis for patients. In our previous research, HIP-55 was found as a novel protein involeved in isoproterenol (ISO) induced cardiac remodeling by using proteomics approaches. Here, we induced cardiac remodeling in HIP-55 transgenic or knockout C57BL/6 mice with injection of isoproterenol hydrochloride (ISO) for 7 days[5 mg/(kg*d)]. The cardiac remodeling was inhibited in transgenic mice and aggravated in knockout mice, suggesting that HIP-55 can inhibit the ISO induced myocardial remodeling. Further mechnism research showed that p38 MAPK inhibitor SB203580 obviously reduced ISO induced myocardial remodeling in neonatal rat ventricular cardiomyocytes and cardac fibroblasts with western blot, realtime PCR and BRDU proliferation assay. While HIP-55 can inhibit the phosphorylation and kinase activation of P38, which were decreased in HIP-55 over-expressed cardiomyocytes and cardiofibroblasts and increased in HIP-55 knock-down cells.Thus, those results indicates that HIP-55 can obviously inhibit the ISO induced myocardial remodeling, and that the mechanism is through negtively regulating p38 MAPK signaling pathway.

PCA050

Effects of detubulation on spatiotemporal properties of Ca transients in sheep atrial myocytes

M.A. Richards, G. Kirkwood, J.D. Clarke and K.M. Dibb

Institute of Cardiovascular Sciences, University of Manchester, Manchester, UK

Transverse (t-) tubules are essential for facilitating the synchronous increase in cytosolic calcium during excitation-contraction coupling in mammalian ventricular myocytes. It has recently been established that atrial cells of large mammals, including humans, also possess substantial t-tubule networks[1]. Here we investigate the functional significance of t-tubules for synchronous Ca release in sheep atrial myocytes.

Myocytes from adult sheep were enzymatically isolated from the left atrial appendage. Formamide was used to detubulate the cells[2]. Cells were bathed in Tyrode's solution and stimulated via patch pipette. Confocal microscopy was used to obtain xy scans of a single z-plane of atrial myocytes using the Ca indicator Fluo-5F AM. Images were sampled at 50Hz and merged to produce pseudo-linescans. T-tests were used for statistical analysis.

Pseudo-linescans showed triggered Ca release in control myocytes was synchronous, with a rapid rise at both sarcolemmal and central regions of the cell. In contrast, detubulated cells showed a rapid Ca rise at sarcolemmal sites and a slow Ca rise at central regions. To quantify the synchronicity of Ca release, rates of Ca rise for each region were plotted as a function of distance from the sarcolemma and fitted with a linear regression. The mean gradient was flat for control cells but was steep for detubulated cells (0.0015 ± 0.0085 vs. -0.075 ± 0.014, n=8-10; P<0.001) indicating a high degree of dyssynchrony. This resulted in a steep gradient for time to peak in detubulated cells (0.0006 ± 0.0014 vs. 0.0232 ± 0.0053, n=8-10; P<0.01). The difference in time to peak between central and sarcolemmal regions was significantly slower in detubulated than control cells (2.1 ± 14.5ms vs. 215.8 ± 39.5ms, n=8-9; P<0.001). Detubulated cells showed a marked latency in central Ca rise (6.4 ± 5.3ms vs. 68 ± 22.5ms, n=8-9; P<0.05). On exposure to isoprenaline (100nM) detubulated cell Ca transients from central regions showed a rapid Ca rise similar to those at the sarcolemmal regions. The steep gradient of dyssynchrony seen in detubulated cells was flattened in the presence of isoprenaline (-0.075 ± 0.014 vs. 0.009 ± 0.02, n=4; P<0.01). However, in spite of an increase in synchronicity of Ca release, the latency of Ca rise was still present (68 ± 22.5ms vs. 57.4 ± 8.6ms, n=4; P>0.05).

These data show that Ca transients of sheep atrial myocytes result from synchronous Ca release at all regions of the cell. Acute loss of t-tubules resulted in dyssynchrony, increased latency and time to peak of Ca transients at central regions of the myocytes. β-adrenoceptor activation improves synchronicity of Ca release in detubulated myocytes but latency of Ca transients at the central regions persists due to the reliance of Ca wave propagation in the absence of t-tubules.

Membrane nanotubes as a novel long distance intercellular connectivity between Cardiomyocytes and Cardiofibroblasts

Y. Zhang

Institute of Vascular Medicine, Peking University Third Hospital, Beijing, China and Key Laboratory of Cardiovascular Molecular Biology and Regulatory Peptide, Ministry of Health, Beijing, China

Background: Intercellular interactions between cardiomyocytes (CMs) and cardiofibroblasts (FBs) are important in the physiological and pathophysiological heart. Understanding such interactions is important for developing effective therapies for heart disease. However, little is known about these interactions until recently. Membrane nanotube (MNT) is a novel structure connecting the mammalian cells over long distance. The classical view is that paracrine and gap junctions are the only forms of "communication" between MCs and FBs. Methods and Results: By membrane dye staining, we observed long, thin membrane nanotubular structures containing actin and microtubules that connected neonatal rat ventricular CMs and FBs. The mean length of WGA-stained membrane nanotubes between CMs and FBs was 13.9±10.4 mm (n=73 of 39 pairs of cells). By single-particle tracking, we observed vehicles moving between CMs and FBs within the membrane nanotubes. By dual colour staining, confocal imaging and flow cytometry, we observed mitochondria exchange between CMs and FBs in a coculture system. By combined atomic force microscopy (AFM) and confocal microscopy, we observed calcium signal propagation from AFM-stimulated CM or FB to unstimulated FB or CM via membrane nanotubes. By membrane and cytoskeleton staining, we observed similar nanotubular structures in adult mouse heart tissue, which suggests their physiological relevance. Conclusion: Our study posts a challenge to the classical "cardiac communication" theory, and suggests that MNT is an important structure for long distance "communication" between cardiac cells.

PCA052

Palmitoylation of the Na pump catalytic subunit

K. Wypijewski[1], J. Howie[1], L. Reilly[1], L. Tian[2], M.J. Shipston[2], M.L. Ashford[1] and W. Fuller[1]

[1]Division of Cardiovascular & Diabetes Medicine, College of Medicine Dentistry & Nursing, University of Dundee, Dundee, UK and [2]Centre for Integrative Physiology, University of Edinburgh, Edinburgh, UK

Acute regulation of the cardiac Na pump by extracellular stimuli is crucial in allowing the heart to match its output to systemic requirements. The Na pump not only plays a critical role in a plethora of transmembrane transport process, electrical excitability and cell volume control but also, by setting intracellular Na, is a primary determinant of cardiac contractility because it determines the set-point for the sarcolemmal sodium-calcium exchanger.

S-palmitoylation is a reversible covalent post-translational attachment of the fatty acid palmitic acid to the thiol group of cysteine, via an acyl-thioester linkage. Palmitoylation can alter enzymatic / ion channel activity, stability or subcellular localisation of the target protein, and this is usually achieved by the recruitment of the palmitoylated cysteine to the lipid bilayer. As such, palmitoylation has the potential to induce substantial changes in protein secondary structure and thus function, through the recruitment of intracellular loops to the inner surface of the membrane bilayer.

We investigated palmitoylation of the catalytic α subunit of the Na pump in ventricular myocytes isolated from adult male Wistar rats. Palmitoylated proteins were purified by resin-assisted capture, and palmitoylation sites identified by differential alkylation of palmitoylated and non-palmitoylated cysteines, followed by analysis by LC-MS/MS against inclusion lists. Cys 374 in the α1 subunit of the Na pump was found palmitoylated. Located within the P (phosphorylation) domain of the α1 subunit which is transiently phosphorylated during the reaction cycle of the pump, C374 lies only 2 amino acids from the central catalytic aspartate (376), the site of this transient phosphorylation, meaning its palmitoylation is highly likely to influence pump activity.

In order to determine which acyl palmitoyl transferase (DHHC-PAT) palmitoylates the Na pump α1 subunit, all 25 mammalian DHHC-PATs were individually transiently overexpressed in HEK-293 cells, and palmitoylation of the endogenous Na pump α1 subunit assessed by immunoblotting after resin-assisted capture. Only expression of DHHC15 significantly increased palmitoylation of the α1 subunit (4.6±1.8 fold over mock transfected control, n=5, mean±SEM $p<0.05$, t-test), implicating this DHHC-PAT in pump α subunit palmitoylation.

DHHC15 is a Golgi-localised DHHC-PAT. We therefore propose that α subunit palmitoylation occurs early in the lifetime of the cardiac Na pump complex, and may represent a mechanism to inhibit futile ATP hydrolysis and / or Na-loading of intracellular compartments by the Na pump during it passage through the secretory pathway. The control of α subunit depalmitoylation upon delivery to the surface membrane may therefore represent a crucial step in controlling the number of active Na pumps at the cell surface.

PCA053

Simultaneous measurement of cytoplasmic and SR calcium during modulation of ryanodine receptor open probability in canine ventricular myocytes

D.J. Greensmith[1], G.L. Galli[1], M.J. Morton[2], C.E. Pollard[2], A.W. Trafford[1] and D.A. Eisner[1]

[1]Unit of Cardiac Physiology, The University Of Manchester, Manchester, UK and [2]Safety Pharmacology, Safety Assessment UK, AstraZeneca R&D, Macclesfield, UK

We have previously shown in rat ventricular myocytes that modulation of ryanodine receptor (RyR) open probability using low concentrations of caffeine has no *maintained* effect on the amplitude of systolic Ca (Trafford *et al*, 2000). We suggested

that the increased RyR open probability was compensated for as the initial increase in systolic Ca enhanced sarcolemmal Ca efflux thus reducing SR Ca content. Here we present data that address two outstanding issues. (1) Are similar results seen in a large animal model? (2) We wished to measure SR Ca content directly rather than, as in our previous work, inferring it from sarcolemmal Ca fluxes.

Canine ventricular myocytes were loaded with Fluo-3 for cytoplasmic Ca measurement or co-loaded with Fluo-3 and the low-affinity Ca indicator, Mag-Fura-2 for cytoplasmic and intra SR Ca measurement respectively and paced at 0.5 Hz under voltage or current clamp.

Under voltage clamp, application of 0.5 mM caffeine initially increased the amplitude of systolic Ca by 115 %. This was associated with a 19 % decrease in Ca influx on the L-type Ca current and a 145 % increase in sarcolemmal Ca efflux. However, within 3 or 4 beats in caffeine, all these parameters recovered to control levels. Upon caffeine washout, we observed an under shoot in the amplitude of systolic Ca which subsequently recovered to control levels. In the steady state, 0.5 mM caffeine reduced SR Ca content (quantified by application of 10 mM caffeine) by 47 % which subsequently recovered during washout.

To directly measure beat by beat SR Ca, myocytes were co-loaded with Fluo-3 and Mag-Fura-2 and paced under current clamp. Upon caffeine application, a 154 % potentiation of systolic Ca was associated with a 755 % increase in the magnitude of systolic SR Ca depletion. Both these parameters rapidly recovered to control levels during caffeine application, coinciding with a beat by beat reduction of SR Ca to 84 % of control. Upon washout, an initial 41 % decrease in systolic Ca was associated with a 55 % decrease in the magnitude of systolic SR Ca depletion. Both these parameters and SR Ca content subsequently recovered to control levels.

These data demonstrate that in a large animal model, modulation of RyR open probability has no maintained effect on the amplitude of systolic Ca. Increasing RyR open probability initially increases systolic Ca leading to reduced Ca influx and enhanced Ca efflux and so a net loss of Ca from the cell. This results in a beat by beat loss of SR Ca to a level that compensates for the increased RyR open probability, at which point the amplitude of systolic Ca is restored. The converse is true during the relative decrease of RyR open probability during wash.

PCA054

Regulation of I_{Ca} by basal protein kinase A activity and its facilitation by caveolin-3 are altered in heart failure in rat ventricular myocytes

S. Bryant[1], C.H. Kong[1], M. Suleiman[2], A.F. James[1] and C.H. Orchard[1]

[1]School of Physiology & Pharmacology, University of Bristol, Bristol, UK and [2]School of Clinical Sciences, University of Bristol, Bristol, UK

The transverse (t-) tubules of cardiac ventricular myocytes show marked changes in structure during heart failure (HF), which lead to decreased synchrony of Ca release and Ca transient amplitude. We have previously shown that stimulation of L-type Ca current (I_{Ca}) by basal protein kinase A (PKA) activity occurs predominantly in the t-tubules and is facilitated by caveolin-3 (Cav-3). However, the effect of HF on such regulation is unknown. We have, therefore, investigated Cav-3 and PKA mediated regulation of I_{Ca} in a rat model of HF.

Myocardial infarction was induced in male Wistar rats (~250g) by ligation of the left anterior descending coronary artery (LAD) under surgical anaesthesia (Ketamine 75 mg/kg, Medetomidine 0.5 mg/kg, *i.p.*) with appropriate analgesia (Buprenorphine 0.05 mg/kg, *s.c.*). Left ventricular myocytes were isolated from ligated (HF) or sham animals 16 weeks after surgery, following removal of the heart under Pentobarbitone (140 mg/kg *i.p.*) anaesthesia. All animal procedures were approved by the University of Bristol ethics committee and conducted in accordance with UK legislation. I_{Ca} was recorded using whole-cell patch-clamp at room temperature. Incubation with TAT-tagged C3SD peptide was used to disrupt normal Cav-3 protein binding (MacDougall et al., 2012); non-incubated cells were used as controls (Con). Cells stained with di-8-ANEPPS were imaged using confocal microscopy. T-tubule regularity was quantified using FFT analysis by plotting the amplitude of the first harmonic as a function of total intensity (TT power). Data are expressed as mean±SEM (n). Statistical significance at $p<0.05$ was determined using Student's t-test or analysis of variance with the appropriate Bonferroni *post hoc* test.

Animals that underwent LAD ligation had significantly increased heart:body weight (Sham 3.3±0.2 (9) vs HF 4.6±0.2 (7) g/kg, $p<0.001$) and lung:body weight (Sham 3.2±0.1 (9) vs HF 3.7±0.1 (7) g/kg, $p<0.05$). HF myocytes had increased cell capacitance (Sham 285±12 (31) vs HF 348±18 (21) pF, $p<0.01$ and reduced TT power (Sham 70.6±9.8 (48) vs HF 35.4±4.7 (58) a.u., $p<0.002$).

Under basal conditions I_{Ca} density was not different between Sham and HF (Sham -6.1±0.2 (31), HF -5.8±0.3 (21) pA/pF, ns). However, after inhibition of basal PKA activity using H-89 (20 μM) I_{Ca} density was lower in HF (Sham -3.0±0.1 (18), HF -2.3±0.1 (14) pA/pF, $p<0.05$). I_{Ca} was reduced by C3SD in sham cells (Sham -6.5±0.4 (16), Sham+C3SD -4.9±0.3 (16) pA/pF, $p<0.01$) but was not affected by C3SD in HF cells (HF –5.6±0.4 (14), HF+C3SD -5.8±0.5 (15) pA/pF, ns).

These data suggest that in HF, under basal conditions, there is increased stimulation of I_{Ca} by basal PKA activity but that the normal coupling of PKA activity to I_{Ca} by Cav-3 is disrupted.

Loss of myocardial nNOS in atrial fibrillation (AF) affects action potential duration: Implications for AF-induced electrical remodelling

X. Liu[1], S. Reilly[1], A. Bueno-Orovio[2], R. Carnicer[1], A. Recalde[1], R. Jayaram[1], B. Rodriguez[3] and B. Casadei[1]

[1]Cardiovascular Medicine, University of Oxford, Oxford, UK, [2]Oxford Centre for Collaborative Applied Mathematics, University of Oxford, Oxford, UK and [3]Computer Science, University of Oxford, Oxford, UK

Rationale: Reduced action potential duration (APD) and lack of APD rate dependent-adaptation are hallmarks of AF-induced electrical remodelling of the atrial myocardium. Understanding the mechanism underlying atrial electrical remodelling in AF is of fundamental importance for the prevention and treatment of AF. We have recently found that nitric oxide synthase (NOS) activity is dramatically reduced in atrial myocytes from goats and patients with AF. Whether loss of NOS activity contributes to the AF-induced atrial electrical remodelling remains to be established.
Methodology: The whole cell current patch clamp technique was used to measure the AP in human and murine isolated atrial myocytes (N: number of patients or mice; n: number of myocytes). AF was induced in mice in vivo by using transoesophageal electrical stimulation. The protein content of constitutive NOSs (nNOS and eNOS) was assessed by Western blotting in atrial lysates. NOS activity was measured by the L-arginine to citrulline assay. Simulations were performed to evaluate the role of decreased nNOS activity in rotor stability in mouse right/left atrial (RA/LA) tissue models.
Results: We found that decreased atrial NOS activity in patients with AF was associated with a significant reduction in nNOS protein expression (by 62%) whereas eNOS was unchanged. To evaluate the role of nNOS on atrial electrical properties, we examined the effects of the nNOS inhibitor, S-methylthiocitrulline (SMTC), or nNOS gene deletion on APD. SMTC induced 38%, 39% and 30% reduction in APD20, APD50 and APD90 respectively in RA myocytes from patients in Sinus Rhythm (SR) (N=8, n=38 control vs. N=8, n=31 cells perfused and dialyzed with SMTC, $p<0.001$) and suppressed the APD rate dependent-adaptation. In murine RA myocytes, inhibition and gene deletion of nNOS reduced APD by 38% and 22%, respectively (N=9, n=35 from $nNOS^{-/-}$ & N=6, n=11 wild type, WT, cells plus SMTC vs. N=10, n=28 control WT cells, $p<0.001$). SMTC had no effect on APD in atrial myocytes from $nNOS^{-/-}$ mice. nNOS inhibition and gene deletion also abolished the physiological RA to LA gradient in APD. In silico simulation indicated that lack of atrial APD gradient promotes rotor stability at the RA/LA junction which may contribute to increased AF propensity. In agreement with these findings, nNOS-deficient mice displayed a 2-fold increase in AF inducibility in response to stimulation ($p<0.05$ vs. WT littermates, N=18 in each group).
Conclusions: In mammalian atrial myocytes, nNOS plays an important role in determining APD, its rate-adaptation and the physiological RA/LA electrical gradient. These findings suggest that the marked loss of nNOS protein and activity in the fibrillating atrial myocardium has potentially important implication for AF-induced electrical remodelling.

PCA056

A molecular modeling approach for understanding mechanism of disease causing mutations in domain C1 of cardiac myosin binding protein C

N. Krishnamoorthy[1], P. Gajendra Rao[1], H.S. Kassem[2], S. Moharem-Elgamal[2], F. Cecchi[3], I. Olivotto[3] and M.H. Yacoub[1,4]

[1]Qatar Cardiovascular Research Center, Qatar Foundation, Doha, Qatar, [2]BA-HCM National Programme, Aswan Heart Centre, Aswan, Egypt, [3]Referral Center for Myocardial Diseases, Careggi University Hospital, Florence, Italy and [4]National Heart and Lung Institute, Imperial College London, London, UK

Hypertrophic cardiomyopathy (HCM) is an inherent heart disease that dysregulate cardiac muscle contraction and several mutations in sarcomeric proteins are reported to be associated with HCM. Recently, in Egypt, we identified three disease causing mutations in cardiac myosin binding protein C (cMyBP-C), which is one of the sarcomeric proteins with multiple-domains (C0-C10). However, structure-function relationship for the mechanism of disease is largely unknown. Here, we describe structural consequences of the three HCM causing mutations, Arg177His, Ala216Thr and Glu258Lys, in domain C1 using molecular modeling techniques (Poornima et al., in press, PLOS ONE). Molecular dynamics simulations and stability analyses showed that the mutations affect the following structural properties of domain C1 i) rigidity, ii) intra-molecular interactions, iii) secondary structural elements and iv) surface electrostatics. The described structural changes (Figure) in domain C1 could distract binding of cMyBP-C to other sarcomeric proteins such as actin and/or myosin and thereby influence Ca2+ signalling and energy supply for contractile function to produce energy depletion. This study provides possible explanations to understand the relationship between structural change and molecular mechanism of the disease.

PCA057

Properties of pro-arrhythmic Ca^{2+} waves in rat ventricular myocytes are altered globally and locally by changes in intracellular pH

K.L. Ford[1], E.L. Moorhouse[1], M. Bortolozzi[1,2] and R.D. Vaughan-Jones[1]

[1]Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK and [2]Department of Physics and Astronomy G. Galilei, University of Padua, Padua, Italy

Intracellular acidosis is a feature of both myocardial ischaemia, where it has been linked to ischaemia-reperfusion injury[1], and heart failure[2]. A decrease in pH_i has been shown to have multiple effects on the calcium handling apparatus[3], leading to the hypothesis that acidosis may drive myocardial pathology via effects on calcium. Here, we show that altering pH_i globally and locally affects multiple parameters of spontaneous Ca^{2+} waves, which may be an arrhythmogenic risk factor. pH_i was altered globally by superfusing with 20-80 mM acetate (acidosis) or 20 mM trimethylamine (alkalosis). Spontaneous Ca^{2+} waves, induced by raising superfusate Ca^{2+}, were linescan-imaged at 37°C in rat isolated ventricular myocytes AM-loaded with fluo-3. Parallel pH_i measurements were made using AM-loaded SNARF-1. Data are mean±SE, *P* values calculated using a paired Student's *t* test. Intracellular acidosis increased spontaneous wave frequency up to 360±62% of control (*P*=0.0002, n=18). This effect was prevented by inhibiting the sarcolemmal Na^+/H^+ exchanger (NHE) with 30 μM 5-(N,N-dimethyl)amiloride, demonstrating Na^+-coupling to intracellular Ca^{2+} dynamics. Under these conditions, waves were suppressed relative to control (to 61±22% of control; *P*=0.0023, n=11), indicating that H^+ may have cardioprotective properties. Intracellular alkalosis also decreased wave frequency to 60% of control after 60 seconds (*P*=0.0048, n=10). Decreasing pH_i increased wave velocity up to 140±3% of control (*P*<0.0001, n=17), while an intracellular alkalosis decreased velocity to 80% of control (*P*<0.0001, n=12). Analysis over a range of pH_i values demonstrated a linear relationship between pH_i and wave velocity. Computational modelling[4] suggests that this may be due to a decrease in cytoplasmic Ca^{2+} buffering; consistent with this, inhibiting NHE had no further significant effect during acidosis. It is likely that pH_i in the ischaemic heart is heterogeneous, therefore to investigate whether differences in pH_i affect local Ca^{2+} properties, we induced a stable pH_i gradient (pH_i 6.6-7.3) in single ventricular myocytes by superfusing two parallel microstreams perpendicular to the cell, one containing normal Tyrode, the other 80 mM acetate[5]. With NHE inhibited, wave initiation was inhibited in the acidic microdomain (31±7% of control;*P*<0.05, n=13) and stimulated in the more alkaline microdomain (164±25%; *P*<0.05, n=13), while wave velocity was increased in the acidic microdomain and decreased in the more alkaline microdomain. Other effects on Ca^{2+} dynamics, including wave decay, also mapped on to the pH_i gradient. We conclude that pH_i locally regulates Ca^{2+} handling and dynamics, and thus pH_i heterogeneity may provide a substrate for aberrant Ca^{2+} signalling in cardiac pathology.

PCA058

The effects of repaglinide on cardiac action potential and ion channels

H. Lee, S. Park and K. Kim

Next-generation Pharmaceutical Research Center, Korea Institute of Toxicology, Daejeon, Republic of Korea

Unfortunately, many non-cardiac drugs have also been reported to cause cardiac events including QT prolongation and/or life-threatening Tosade de points (TdP). Recent reports are shown that the diabetic patients with more pronounced QT abnormalities and cardiovascular complications. Repaglinide is well-known antidiabetic drug. Therefore, it is important that the evaluation of the potential effects of repaglinide on cardiac repolarization.

In the present study, we examined the in vitro action potential (AP) assay with isolated rabbit Purkinje fiber (New Zealand White rabbits, 2.5-3 kg) to predict the potential of repaglinide to induce these undesirable adverse effects on the heart. Furthermore, we examined the effects of repaglinide on the major cardiac ion channels transiently transfected with the hERG(IKr), KCNQ1/KCNE1(IKs), KCNJ2(IK1) and SCN5A(INa) cDNA in HEK293 cells and the native voltage-gated Ca2+ channels in rats (Sprague-Dawley, 250-350 g, male) ventricular myocytes using the whole-cell patch clamp technique. Pooled data are expressed as means ± S.E.M., and compared by ANOVA followed by Dunnett's test. According to the results, repaglinide at 30 μM significantly prolonged the action potential duration at 50% levels of repolarization (APD50, from 156.2 ± 4.3 to 179.1 ± 4.3 ms, n=4, P<0.05) and the action potential duration at 90% levels of repolarization (APD90, from 241.6 ± 7.4 to 278.9 ± 4.5 ms, n=4, P<0.01). According to ion channel studies, these effects could be induced by K+ channels blocking especially hERG and IKs. However, repaglinide at 100 μM significantly shortened the APD50 (156.2 ± 4.3 to 120.0 ± 7.9 ms, n=4, P<0.01) and APD90 (from 241.6 ± 7.4 to 190.9 ± 8.6 ms, n=4, P<0.01). In addition, the 100 μM repaglinide caused decrease of the maximum velocity of phase 0 (Vmax) from 269.2 ± 13.1 to 179.8 ± 9.1 V/s (n=4, P<0.01). These effects could be induced by the blocking of depolarizing currents for Na+ and Ca2+ channels. In the ion channel studies, repaglinide did inhibit the all of the tested ionic currents in a concentration-dependent manner except IK1. Among these ion channels, the voltage-gated Ca2+ channel was the most susceptible to repaglinide.

The drug-induced shortening of the QT interval could potentially increase the ventricular tachycardia and the ventricular fibrillation risk of sudden death. Therefore, all patients taking this drug should be more carefully monitored for cardiac events.

PCA059

Structural characteristics of the sinus node and surrounding atrial tissue in the goat heart

Z. Borbas, J. Caldwell, A. Vohra, A. Hoschtitzky, M.R. Boyett, C.J. Garratt and H. Dobrzynski

Cardiovascular Research group, University of Manchester, Manchester, UK

Introduction: Sinus node (SN) dysfunction is a common clinical condition that is accounted for 50% of permanent pacemaker implantation. In order to examine the value of the goat as a model of human SN function and dysfunction we examined the structure of the SN and the surrounding right atrium in this species.
Method: Right atria were harvested from 4 humanely killed goats. Under 3% Isoflurane anaesthesia, two of the 4 animals underwent an incremental protocol of epicardial SN ablation, sufficient to cause at least a 50% fall in heart rate, in order to determine the functional extent of the SN. All preparations were frozen, serially sectioned at 1 mm intervals and stained for histology using Masson trichrome technique. The extent and morphology of the native and ablated SN were determined. For verification of the histology, immuno-staining for Connexin43 (Cx43; a negative marker for the SN) and Na/Ca exchanger (NCX, a membrane-bound ion channel protein; positive marker for of all cardiomyocytes) was used on selected tissue sections. Images were taken with light and confocal microscopy.
Results: The goat SN was located in the intercaval region (ICR) parallel to the crista terminalis (CT) and extended 2/3 of its length in the long axis. In the short axis, the centre of the SN occupied the full thickness (2mm) of the intercaval region (panel A). The SN, as in other species, consisted of cells which were small, lightly stained (compared to atrial myocytes) and embedded in a network of connective tissue (panel B, C) [1,2]. All myocytes expressed NCX but not Cx43 unlike atrial myocytes.
We also observed a transitional zone (TZ), (panel D) arising on the endocardial side of the CT (Panel A) which extended caudally beyond the SN. The morphology of TZ was intermediate to nodal and atrial tissue; conaining atrial as well as nodal cells..In addition, TZ contained an intermediate cell-type which histologically was similar to atrial myocytes, but lacked expression of Cx43; similarly to the novel paranodal area recently described in the human heart[3] .
In the experimental goats, the size and location of the ablated area corresponded to that of the healthy SN in the control group, but it spared an area caudal to the SN and did not involve the TZ.
Conclusions: The SN in the goat is associated with an extensive adjacent region of transitional cells, similar to that recently described in the human. The natural function of this region is currently unknown but may provide a useful target for novel methods of "biological pacemaking" currently in development.

PCA060

Angiotensin II receptor blocker and PPAR-gamma agonist, telmisartan, delayed inactivation of cardiac Nav1.5: A novel drug mechanism

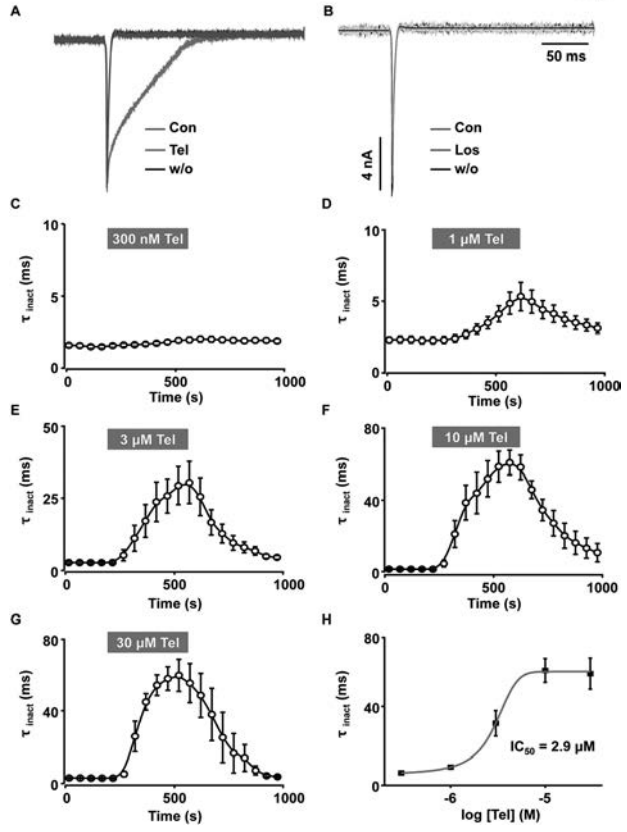
H. Kim, J. Youm, S. Lee, K. Ko, B. Rhee, N. Kim and J. Han

National Research Laboratory for Mitochondrial Signaling Laboratory, Department of Physiology, College of Medicine, Cardiovascular and Metabolic Disease Center, Inje University, Busan, Republic of Korea

Telmisartan is an angiotensin II receptor blocker and partial peroxisome proliferator-activated receptor gamma agonist that modulates the renin-angiotensin-aldosterone system. It is used primarily to manage hypertension, diabetic nephropathy, and congestive heart failure. Recent studies have reported that myocardial infarction (MI) has occurred in telmisartan-treated patients.The purpose of the study was to investigate the specific conditions and underlying mechanisms that may result in telmisartan-induced MI. We evaluated the effect of telmisartan on whole hearts, cardiomyocytes, and cardiac sarcolemmal ion channels. Hearts of 8-week-old male Sprague–Dawley rats were perfused with 3, 10, 30, or 100 μM telmisartan or losartan, or normal Tyrode's solution (control) for 3 hours. We found that telmisartan induced myocardial infarction, with an infarct size of 21% of the total at 30 μM ($P<0.0001$) and 63% of the total area at 100 μM ($P<0.001$). Telmisartan also induced cardiac dysfunction (e.g., decreased heart rate, diminished coronary flow, hypercontracture, and arrhythmia). Confocal microscopy demonstrated that 30 μM telmisartan significantly elevated intracellular Ca2+ level lead-

ing to hypercontracture and cell death. Patch clamp analysis of isolated cardiomyocytes revealed that telmisartan induced Na+ overload by slowing the inactivation of voltage-gated Na+ current (INa), activating the reverse-mode of Na+-Ca2+ exchanger activity, and causing Ca2+ overload. Telmisartan significantly delayed inactivation of the voltage-gated Na+ channel causing cytosolic Na+ overload, prolonged action potential duration, and subsequent Ca2+ overload. Above 30 μM, telmisartan may potentially cause cardiac cell death and MI.

Fig. 7



Telmisartan delays inactivation of voltage-dependent Na+ channels in ventricular myocytes. Effect of 30 μM telmisartan (A, red) and 30 μM losartan (B, green) on INa. Cells were held at -80 mV, and step pulses to -50 mV were applied every 10 s to activate INa. Telmisartan (30 μM) delayed inactivation of the inward current without affecting rate of activation or amplitude (n=21), whereas the same concentration of losartan affected neither time course nor amplitude of the inward current (n=3). The prolonged INa fully recovered by switching to NT solution. C–G, Time course of INa inactivation during telmisartan perfusion (300 nM, n=6; 1 μM, n=6; 3 μM, n=11; 10 μM, n=7; 30 μM, n=4). H, The data fit well to the Hill equation (EC50=2.94±0.07 μM).

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Bisphenol A decreases *in vitro* atrial contractility and also attenuates Phenylbiguanide evoked reflexes after chronic exposure in anaesthetized rats

J. Pant, P. Ranjan, M.K. Pant and S.B. Deshpande

Physiology, Institute of Medical Sciences, Banaras Hindu University, Varanasi, Uttar Pradesh, India

Bisphenol A (BPA), an endocrine disruptor, is used in the manufacturing of plastics. BPA is reported to produce a number of reproductive defects and is even associated with behavioural abnormality, diabetes and deranged liver enzymes. However, the knowledge on toxic effects of BPA on cardiovascular system is limited. Therefore the present study was performed to examine the effects of BPA on spontaneously beating rat right atrial preparation *in vitro* as well as to see the changes after chronic exposure to BPA in *in vivo* conditions. The experiments were performed using adult female rats of Charles Foster strain weighing 150-200 grams after obtaining clearance from the ethical clearance committee of the institute. The study was divided in two groups. In group 1, *in vitro* isometric contractions of rat right atria were recorded. Effect of cumulative concentration of BPA on atrial contractions was obtained in the absence or presence of antagonists. BPA (0.1–100 μM) decreased the rate and the force of atrial contractions in a concentration dependent manner. The BPA-induced changes were blocked after pretreatment with N- ω- nitro-L- arginine methyl ester (L- NAME, a nitric oxide synthase inhibitor) or methylene blue (a guanylyl cyclase inhibitor) whereas atropine (muscarinic receptor blocker) did not block the BPA-induced changes in atria.

In group 2, to study the effect of chronic exposure of BPA, the animals were ingested pellets with BPA (2 μg/kg body weight/day) or without BPA (time-matched control) for 30 days. Further, the animals were anaesthetized with urethane (1.5 gm/kg bw; i.p.) and prepared for recording blood pressure, ECG and respiratory excursions. Phenylbiguanide (PBG) 10 μg/kg body weight was injected through jugular vein to evoke cardio-pulmonary reflexes in these animals. Thereafter, the rats were killed using excess dose of urethane and the lungs and heart were excised and processed for histopathological examination. In time-matched control rats, PBG produced bradycardia, hypotension and tachypnoea over a period of time. In BPA treated group, the PBG-induced heart rate and respiratory frequency changes were attenuated significantly. The histological findings of the lungs revealed emphysematous and consolidative changes in BPA treated group whereas in case of heart, there was rupture of myofibrils with edematous changes.

The present results indicate that BPA produces cardiac toxicity by producing acute and chronic changes. Acute changes were seen as decreased atrial contractility *in vitro* involving NO-dependent G-cyclase signaling mechanisms. The chronic changes manifested as lowered blood pressure and heart rate along with attenuation of cardio-respiraory reflexes. In addition there were degenerative changes in lungs and heart to produce the effects of chronic exposure.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Myofilament basis analyses of afterload dependent increasing in crossbridge formation in ejecting rat heart

Y. Tamura[1], K. Horiuchi[2], T. Miyasaka[3] and J. Shimizu[2]

[1]Thoracic and Cardiovascular Surgery, Nara Medical University, Kashihara, Nara, Japan, [2]Clinical Radiology, Hiroshima International University, Higashi-Hiroshima, Hiroshima, Japan and [3]Health Care Science, Himeji Dokkyo University, Himeji, Hyogo, Japan

Myofilament basis mechanism of afterload-dependent increase in contractile force is still remained unclear (1). The purpose of this study is to investigate whether increasing afterload cor-

relate with myosin head proximity to actin filaments and presumably crossbridge activated during contractions. We used eight male Wistar rats anesthetized by pentobarbital (50mg/kg, ip). We used x-ray diffraction analyses of beat-to beat contractions in spontaneously beating rat hearts under open-chest conditions simultaneous with recordings of left ventricular (LV) pressure and volume(2, 3). Aortic occluder was placed at descending aorta to increase afterload. We recorded x-ray diffraction patterns of the LV anterior free wall before and after aortic occlusion to determine the change in intensity ratio (I1,0/1,1) and myosin filament lattice spacing (D1,0). We found significant change neither in end-diastolic I1,0/1,1 nor D1,0, indicating that the proportion of myosin heads in proximity to actin filaments and myosin filament lattice spacing were unchanged by increasing afterload. Peak systolic I1,0/1,1 decreased significantly more after aortic occlusion than before aortic occlusion. Increase in D1,0 during contraction was significantly reduced after aortic occlusion than before aortic occlusion. A significant increase in myosin head proximity to actin filaments with increasing afterload correlated with increase in LV end-systolic pressure. A significant reduction in changes of D1,0 between diastole and systole with increasing afterload correlated with decrease in LV stroke volume. Since sarcomere length of cardiomyocyte related inversely with D1,0 because of constant cellular volume, reduced D1,0 change during contraction means prevention of sarcomere shortening with increasing afterload. These findings support a role of arterial resistance in determining LV stroke volume as the cardiovascular interaction.

PCA064

Stimulation of I_{Ca} by protein kinase A in the t-tubules of rat cardiac ventricular myocytes is facilitated by caveolin-3

S. Bryant, T. Kimura-Wozniak, C.H. Orchard and A.F. James

School of Physiology & Pharmacology, University of Bristol, Bristol, UK

In cardiac ventricular myocytes many of the key proteins involved in excitation-contraction coupling, including L-type calcium channels (LTCC), are located predominantly at the transverse (t-) tubules. Protein kinase A (PKA)-mediated stimulation of L-type Ca current (I_{Ca}) also occurs predominantly at the t-tubules. Caveolin-3 (Cav-3) has been implicated in the localization of PKA activity to macromolecular complexes. We have, therefore, investigated whether Cav-3 plays a role in the stimulation of I_{Ca} by PKA in the t-tubules of rat ventricular myocytes.

Ventricular myocytes were isolated from the hearts of male Wistar rats (250-300 g) killed either by cervical dislocation or under pentobarbitone (140 mg/kg *i.p.*) anaesthesia in accordance with UK legislation. I_{Ca} was recorded using the whole-cell patch-clamp technique. From a holding potential of -80 mV, a 100 ms step depolarisation to -40 mV was used to inactivate I_{Na}, followed by a 500 ms step depolarisation (to voltages between -50 and +80 mV) to activate I_{Ca} (0.2 Hz; room temperature). Standard immunohistochemical techniques were used in conjunction with confocal microscopy to determine the localization of Cav-3, total LTCC (tLTCC) and phosphorylated LTCC (pLTCC). Incubation with TAT-tagged C3SD peptide (C3SD) was used to disrupt normal Cav-3 protein binding (MacDougall et al., 2012). Scrambled peptide (Scram) and non-incubated cells (Con) were used as controls. β_2-adrenoceptor stimulation was achieved using zinterol (1-10 μM) applied to cells pre-exposed to atenolol (10 μM). Detubulation (DT) was achieved by exposing cells to 1.5M formamide (Kawai et al., 1999). Data are expressed as mean±SEM (n cells). Statistical analysis was performed by analysis of variance (1 or 2 way) with the appropriate Bonferroni *post hoc* test; significance was taken at $p<0.05$.

In control cells, I_{Ca} density was significantly reduced by C3SD and unaffected by Scram peptide (Con -7.6±0.3 (11), Scram -8.0±0.4 (9), C3SD -5.4±0.2 (15) pA/pF, $p<0.0001$ C3SD vs Scram). However, in detubulated cells C3SD did not decrease I_{Ca} (DT -4.7±0.2 (5), DT+C3SD -4.2±0.4 (6) pA/pF, ns). C3SD had no effect on the distribution of staining of Cav-3 or tLTCC but significantly altered the distribution of pLTCC staining.

The PKA inhibitor H-89 decreased I_{Ca} by 53±3% in Con, but by only 28±10% in the presence of C3SD ($p<0.001$), to a level that was not significantly different from in the presence of H-89 alone (Con -3.6±0.5 (5), C3SD -3.7±0.3 (5) pA/pF, ns). The increase of I_{Ca} induced by zinterol was inhibited in cells incubated with C3SD.

These data are consistent with the notion that Cav-3 plays an important role in mediating the localised stimulation of t-tubular I_{Ca} by basal PKA activity and in response to β_2-adrenoceptor stimulation.

Cardiomyocytes from creatine deficient AGAT mice show no changes in mitochondrial organization and cellular compartmentation

S. Kotlyarova[1], M. Mandel[1], N. Sokolova[1], D. Aksentijevic[2], C.A. Lygate[2], S. Neubauer[2], M. Vendelin[1] and R. Birkedal[1]

[1]Laboratory of Systems Biology, Institute of Cybernetics at TUT, Tallinn, Estonia and [2]Department of Cardiovascular Medicine at Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK

In cardiac muscle, the creatine kinase (CK) system temporally buffers ADP and ATP concentrations near sites of ATP production and consumption. It has also been suggested to be an important spatial buffer facilitating the transport of ADP and ATP. This was corroborated by a study of CK knockout mice,

where cardiac fibers exhibited changes in mitochondrial organization and functional compartmentation – potentially to diminish diffusion distances between mitochondria and ATPases. However, a recent study on cardiomyocytes from creatine-deficient guanidinoacetate methyltransferase (GAMT) knockout mice showed no effect on mitochondrial organization and compartmentation. It has been suggested that in GAMT-/- mice, accumulated guanidinoacetate can be used as a substrate instead of creatine. Therefore, we studied the same parameters in L-arginine:glycine amidinotransferase (AGAT) mice, which are also creatine-deficient, but do not accumulate guanidinoacetate. Mice received an i.p. injection of 250U heparin, and were anesthetized with ketamine/dexmedetomidine mixture (150 mg/kg and 0.5mg/kg, i.p.respectively). Three-dimensional mitochondrial organization at whole cell level was assessed by confocal microscopy. Kinetic measurements on permeabilized cardiomyocytes included the affinity of oxidative phosphorylation to exogenous ADP and ATP, competition between mitochondria and pyruvate kinase for ADP produced by ATPases, ADP-kinetics of endogenous pyruvate kinase and ATP-kinetics of ATPases. Tibial length of AGAT-/- mice was similar to that of AGAT+/+ mice, but body weight was significantly lower. Our results show surprisingly little difference between cardiomyocytes of AGAT-/- and AGAT+/+ mice. We did find that the protein content of AGAT-/- cardiomyocytes was approximately two times lower than that of AGAT+/+ cardiomyocytes. However, visual inspection of mitochondrial organization suggests no essential difference. Also, when respiration is related to the number of cardiomyocytes, there is no difference in the kinetics of respiration and ATPases. Thus, our data so far suggest no differences in cardiomyocyte mitochondrial organization and cellular compartmentation between AGAT-/- and AGAT+/+ mice. We conclude that the lack of compensatory changes in mitochondrial organization and cellular compartmentation in AGAT as well as GAMT mice raise questions regarding the importance of the CK system as a spatial buffer.

Phospholamban ablation reduces the propensity for triggered activity in CPVT transgenic heart cells despite increased SR Ca^{2+} load

K. Gusev[1] and S.E. Lehnart[1,2]

[1]Department of Cardiology & Pulmonology, University of Göttingen, DZHK, Göttingen, Germany and [2]BioMET, University of Maryland, Baltimore, MD, USA

The cardiac ryanodine receptor (RyR2), the principal Ca^{2+} release channel of the heart, is affected by patient mutations and catecholaminergic stress causing defective channel closure, irregular Ca^{2+} triggered action potentials (tAPs), and a ventricular arrhythmia syndrome (CPVT). Based on results obtained in heterologous overexpression models of CPVT mutant RyR2 channels, other groups suggested that catecholaminergic stimulation may lead to triggered activity by reducing the threshold for store overload-induced Ca^{2+} release. We have previously shown that heterozygous RyR2-R2474S ($RyR2^{RS}$) knock-in mice reproduce the characteristic patient phonotype of CPVT. To clarify the physiological arrhythmia mechanism, we evaluated phospholamban deficient ($PLN^{-/-}$;$RyR2^{RS}$) cells with constitutive sarcoplasmic reticulum (SR) Ca^{2+} store overload.

Double transgenic model: heterozygous $RyR2^{RS}$ knock-in mice were crossed with $PLN^{-/-}$ mice to produce $RyR2^{RS}$;$PLN^{-/-}$ mice established in the C57Bl6 background. Electrophysiology: in vivo ECG as well as current-clamp combined with intracellular Ca^{2+} imaging of isolated ventricular myocytes (37C, fluo-3) was used to evaluate the influence of SR Ca^{2+} load on arrhythmogenic behavior. Comparing $RyR2^{RS}$;$PLN^{-/-}$ vs. $RyR2^{RS}$;$PLN^{+/+}$ mice showed for PLN deficient RS cells: (1) significant QT interval shortening (60±2 ms vs. 68±2 ms, respectively; $p<0.05$); (2) significant action-potential shortening (APD90: 89±4 ms vs. 117±8 ms, respectively; $p<0.05$); (3) significantly accelerated Ca^{2+} transient decay (28±2 ms vs. 69±5 ms, $p<0.001$); and (4) significantly increased SR Ca^{2+} load ($\Delta F/F0$: 9.7±1.6 vs. 5.3±1.4, respectively; $p<0.001$). (5) As expected, acute β-adrenergic stimulation with 30 nM isoproterenol resulted in no further increase of SR Ca^{2+} load in $PLN^{-/-}$ ($\Delta F/F0$: $RyR2^{RS}$;$PLN^{-/-}$ 8.1±2.7 vs. $RyR2^{RS}$;$PLN^{+/+}$ 7.0±1.7; n.s.). (6) Despite maximal, constitutive SR Ca^{2+} loading in $RyR2^{RS}$;$PLN^{-/-}$ cardiomyocytes, the occurrence of tAPs during β-adrenergic stimulation was significantly decreased in $RyR2^{RS}$;$PLN^{-/-}$ cells ($RyR2^{RS}$;$PLN^{+/+}$: 9 out of 12 cells (75%); $RyR2^{RS}$;$PLN^{-/-}$: 1 out of 10 cells (10%) had tAP; $p<0.05$).

In summary, our data suggest that maximal upregulation of SERCA2a activity in $PLN^{-/-}$ (1) leads to increased SR Ca^{2+} load and accelerated cytosolic Ca^{2+} removal, which shortens the APD and the QT interval in vivo; and (2) decreases the propensity for tAPs in the context of a highly arrhythmogenic CPVT model with significantly increased diastolic SR Ca^{2+} leak. This suggests that, contrary to expectation, increased SR Ca^{2+} per se, at levels occurring during catecholaminergic stress, may not trigger APs under physiological conditions. An increased susceptibility of $RyR2Ca^{RS}$ cells for tAPs might be blunted by accelerated SR Ca^{2+} uptake and altered diastolic Ca^{2+} handling dynamics.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA068

Biochemical phenotype of a human phospholemman mutation

J. Walker[1], E. Johnston[1], J. Howie[1], H. Parry[1], A. Cassidy[2], M. Shattock[3], C. Palmer[1] and W. Fuller[1]

[1]Division of Cardiovascular & Diabetes Medicine, University of Dundee, Dundee, UK, [2]Human Genetics Unit, University of Dundee, Dundee, UK and [3]Cardiovascular Division, King's College London, London, UK

Phospholemman (PLM) regulates the cardiac Na pump. Unphosphorylated PLM inhibits the pump, and PLM phosphorylation at S63 and T69 (by PKC), and S68 (by PKA or PKC) causes pump activation. Abnormal phosphorylation of PLM is well established in cardiac hypertrophy and failure. We investigated whether genetic polymorphisms in PLM underlie left ventricular hypertrophy (LVH) by sequencing PCR-amplified PLM exons from anonymised genomic DNA from the Go-DARTS database. Inclusion criteria were age <55, systolic blood pressure <140mmHg, BMI <30kgm^{-2}, and moderate-severe LVH

according to echocardiography. 2 out of 43 individuals possessed the same non-synonymous missense coding variant: a C to T transition in position 1 of the codon encoding arginine 70 in PLM exon 7, resulting in the mutation R70C.
The R70C PLM phenotype was investigated by expressing wild type (WT) and R70C PLM in HEK293 cells. Phosphorylation induced by activating PKA (10μM forskolin) and PKC (300nM PMA) was measured by phosphospecific immunoblotting, and expressed relative to WT or R70C-expressing cells treated with vehicle. Phosphorylation of WT and R70C PLM by PKA at PLM-S68 was unchanged (2.0±0.3 fold increase over vehicle-treated for WT, 1.8±0.1 fold increase for R70C, mean±SEM, n=4). PKC-induced phosphorylation of PLM-S63 was also unchanged, but R70C PLM was phosphorylated less than WT at S68 following activation of PKC (1.8±0.2 for WT, 1.0±0.2 for R70C, n=4, $p<0.05$, t-test), suggesting mutation of the arginine at position +2 to S68 had altered this consensus PKC phosphorylation site. We also measured cell surface localisation (membrane-impermeable biotinylation reagents) and palmitoylation (resin-assisted capture of acylated proteins) of WT and R70C PLM. A greater fraction of R70C PLM than WT was found at the cell surface (R70C 3.8±2 fold more enriched than WT, n=3), suggesting a proposed ER retention motif in PLM was also disrupted. A greater fraction of R70C PLM was palmitoylated than WT (53±10% vs 29±5%, n=4, $p<0.05$), possibly due to this enhanced traffic to the cell surface.
Rs61753924, the single nucleotide polymorphism (SNP) underlying PLM R70C, occurs at 0.1% frequency in the 1000 Genomes Project. We investigated the frequency of this SNP in LVH case and non-LVH controls: 19 out of 393 LVH cases (4.8%) and 10 out of 266 (3.7%) controls were positive for rs61753924 (odds ratio = 1.14, $p>0.05$).
In conclusion, PLM R70C shows reduced phosphorylation at S68 by PKC. In vivo PLM is significantly phosphorylated at rest by PKC, so the reduced phosphorylation and enhanced cell surface localisation and palmitoylation of R70C PLM may lead to reduced Na efflux via the pump. Preliminary analysis indicates that the presence of SNP rs617539241 is not a risk factor for the development of LVH, but is enriched in the local population.

PCA069

Popdc genes and cardiac pacemaking: The molecular basis of genetic redundancy

S. Simrick[1], R. Schindler[1], R. Kreutzer[2], M. Krüger[3], T. Braun[3], C. Terracciano[1], L. Fabritz[2] and T. Brand[1]

[1]National Heart and Lung Institute, Imperial College London, London, UK, [2]Cardiovascular and Respiratory Sciences, University of Birmingham, Birmingham, UK and [3]Max Planck Institute for Heart and Lung Research, Bad Nauheim, Germany

Popeye domain containing (Popdc) genes encode a novel class of cAMP-binding proteins. Functional analysis of *Popdc1* and *-2* genes in mice indicate a potential role in the chronotropic response to β-adrenergic signalling, with single null mutants displaying a stress-induced bradycardia.[1] The overlapping phenotype in both mutants is age-dependent, suggesting the presence of genetic redundancy. Here we report our preliminary analysis of *Popdc1;Popdc2* double knockout (P12dKO) mice and the functional interactions of Popdc1 and -2 at the protein level.
Popdc1;Popdc2 double heterozygous (P12dHET), P12dKO, and wild type (WT) age-matched control male mice were subjected to telemetric ECG analysis at rest and during physical stress (6min swim, 15min recovery). In accordance with our single null mutant analysis, no significant difference was observed in the heart rates of 3 month old mice at rest (WT 514±34bpm, n=7; P12dHET 547±36bpm, n=5, two-tailed t-test p=0.14; P12dKO 552±36bpm, n=3, two-tailed t-test p=0.20). However, in contrast to the single null mutants where the stress-induced bradycardia was not observed until 5.5 months of age, the 3 month old P12dKO mice had a blunted response to physical stress (WT 39% increase in heart rate, n=7; P12dHET 32%, n=5, two tailed t-test p=0.35; P12dKO 18%, n=3, two-tailed t-test p=0.01). A blunted increase in heart rate in response to physical stress is consistently seen in P12dKO older mice (>9 months), although not exacerbated compared to P1KO mice (WT 719±14bpm, n=5; P1KO 593±39bpm, n=5; P12dKO 665±24bpm, n=6, WT vs P12dKO two-tailed t-test $p<0.01$), which suggests that during early postnatal development the two Popdc genes can functionally compensate each other and act in the same functional context since the loss of either gene is causing a pacemaker deficiency and phenotypic severity does not increase if both Popdc genes are missing.
Immunohistochemistry revealed that both Popdc1 and -2 proteins are expressed throughout the heart, with enhanced expression in the cardiac conduction system. At the single cell level both proteins are located at the plasma membrane, intercalated disks and in T-tubules. To identify new interaction partners for Popdc proteins, we performed co-immunoprecipitation followed by mass spectrometry. By this screen Ankyrin-G and -B and the Na^+/Ca^{2+} exchanger NCX1 were identified and subsequently confirmed by Western Blot as interacting proteins. Furthermore, we were able to demonstrate an interaction of Popdc1 and 2, suggesting that members of the Popdc family are interacting with each other and thereby acting in the same functional context. This may explain the overlapping phenotypes of *Popdc1* and *-2* mutants and the earlier manifestation of the bradycardia in P12dKO mice. Further analysis at the protein, cell, and organismic level, will help to define the role of Popdc proteins in cardiac stress adaptation.

PCA070

Potential antiarrhythmic effects of paeoniflorin and paeonol extracted from the paeoniaceae family

S. Lee[1,2], P.J. Noble[1], Y. Ma[1], Y. Earm[3] and D. Noble[1]

[1]Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK, [2]Department of Physiology, College of Korean Medicine, Sangji University, Wonju, Republic of Korea and [3]Department of Physiology, College of Medicine, Seoul National University, Seoul, Republic of Korea

Paeoniflorin and paeonol are major components found in the Paeoniaceae family such as *Paeonia lactiflora* Pallas and *Paeonia suffruticosa* Andrews. *Paeonia lactiflora* Pallas has traditionally been used to relieve spasmodic abdominal pain as well

as muscle stiffness and *Paeonia suffruticosa* Andrews has been used to enhance blood flow and to relieve joint pain in Korea, China and Japan. Current research has shown that paeoniflorin has protective effects in acute myocardial ischemia *via* improving coronary blood flow and blocking the L-type calcium channels. It has also been reported that paeonol blocked the voltage-gated sodium channels. However, there is lack of research to reveal the relationship between cardiac function and blockade of ion channels by both compounds.
In this study, therefore, we aim to investigate whether paeoniflorin and paeonol have antiarrhythmic effects *via* modulating cardiac ion channels. We collated the effects of paeoniflorin and paeonol on multiple ion channels such as the fast sodium channel, the L-type calcium channel, and the rectifying potassium channel from published papers. To incorporate the information on multi-channel block, we computed the effects using the mathematical cardiac model of guinea-pig ventricular cell (Noble 1998 model) and induced early afterdepolarizations (EADs) to simulate what would be an arrhythmia in the whole heart. We then showed that both paeoniflorin and paeonol enabled recovery of the cardiac ventricular action potential from EADs through blocking of the cardiac L-type calcium channel and sodium channel effectively.
This finding, therefore, suggests that paeoniflorin and paeonol possess antiarrhythmic activity and they and their original herbs can be potential candidates as antiarrhythmic drugs. .

Principles of Membrane and Protein Network Organization in Health and Disease

T. Kohl[1,2], E. Wagner[1,2], S. Brandenbúrg[1,2], U. Parlitz[3,2], J.W. Lederer[4] and S.E. Lehnart[1,5]

[1]Dept. of Cardiology and Pneumology, University Medical Center Göttingen, Germany, Goettingen, Germany, [2]Heart Research Center Goettingen, Göttingen, Germany, [3]Biomedical Physics Group, Max Planck Institute for Dynamics and Self-Organization, Göttingen, Germany, [4]Center fo Biomedical Engineering and Technology, University of Maryland, Baltimore, MD, USA and [5]DZHK (German Center for Cardiovascular Research), site Göttingen, Germany

In heart muscle cells both longitudinal and transversal architectures along the main cell axises represent important building principles that overcome challenging local conditions considering cell size versus cellular metabolic, proteomic and energetic needs. Furthermore, the specific cell volume is occupied by myofilaments that are aligned with mitochondria and the endo/sarcoplasmic reticulum network (SR), which is tightly associated with a highly branched internal sarcolemmal membrane network, the T-tubules (TT). TTs distribute electrochemical signals and nutrients to intracellular Ca2+ release nanodomains and organelles that involve the junctional SR (jSR).
Here we present fundamental properties of the highly branched T-tubule (TT) network as revealed by STED microscopy in isolated mouse cardiomyocytes. Healthy myocytes exhibit longitudinal and transversal components at similar frequencies. Yet, after myocardial infarction the specific micro-scale organization of TT membranes changes leading to a significant increase of longitudinal components and increased network branching, and overall to increased network complexity and spatial dysfunction.
In addition, it remains unclear how TTs interface with the microtubule (MT) system and whether MTs contribute to the TT membrane remodeling described above. MTs have been functionally associated with the organization of SR terminal cisternae and sub-membrane scaffolds (in skeletal muscle) and CaV1.2 targeting to T-tubules (in heart). Therefore, we further examined the MT network architecture and pathological changes. We found predominantly longitudinal MT components with more complex network patterns in the periphery of cells (cortex) as compared to deep internal MTs. Our data suggest, that MT branching occurs at major functional points where dispersed Golgi organelles can be locally identified. Moreover we compare microtubule (MT) networks before and after myocardial remodeling after gradient-controlled aortic banding, which will be presented.
In conclusion, quantitative analysis of membrane and protein networks showed important properties of spatial organization and suggest local mechanisms of remodeling that may contribute to intracellular Ca2+ release heterogeneity.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Simvastatin's effects on muscle are temporally defined and tissue specific

D.A. MacDougall, S.D. Pugh, A. Schorah, W. Rennie and S. Calaghan

School of Biomedical Sciences, University of Leeds, Leeds, UK

Cellular cholesterol is regulated by uptake, *de novo* synthesis, storage and efflux. Statins are inhibitors of HMG CoA reductase, an enzyme governing the rate limiting step in cholesterol synthesis. Statin treatment will initially decrease free cellular cholesterol but this in turn will promote expression of proteins responsible for cholesterol uptake (LDL receptors) and synthesis (HMG CoA reductase) and decrease expression of proteins involved in its storage as cholesteryl esters (acyl CoA cholesterol transferase) and efflux (caveolin) *via* sterol regulatory elements (SRE) in promoter regions. It has recently been shown that cholesterol efflux pathways are the main means by which (neonatal) cardiac myocytes regulate their cholesterol (Reboulleau *et al*., 2012).

We have compared the effect of acute and chronic statin treatment on cardiac and skeletal muscle. In adult rat ventricular myocytes exposed to 10 μM simvastatin for 48 h in culture, cholesterol levels were reduced by 30%, and a corresponding decrease in caveolin 3 expression was seen (cells from n=3-4 hearts; P<0.05; Student's t-test). By contrast, myocardium from adult rats treated with 40 mg/kg simvastatin by oral gavage daily for 2 weeks showed no change in cholesterol (0.38 ± 0.01 *vs*. 0.38 ± 0.02 μg/mg total protein; n=6 hearts; P>0.05). Despite this, caveolin 3 expression was reduced by 40% in statin-treated animals (P<0.05). These data are consistent with the concept that, following 2 weeks of statin treatment, SRE-dependent decreases in caveolin 3 expression act to return cellular cholesterol to normal levels by attenuating efflux pathways. However, normalisation of cholesterol at this time point is not common to all muscle. In *gastrocnemius* type II skeletal muscle from the same group of animals, cholesterol levels were lowered by 70% (P<0.05), despite an equivalent reduction in caveolin 3 expression (P<0.05). This indicates that skeletal muscle lacks the ability to regulate cholesterol homeostasis to the extent observed in cardiac muscle.

Our data suggest that the effects of statins are temporally defined, with acute statin treatment *in vitro* providing a snapshot of early cardiac statin effects before SRE-dependent changes in caveolin expression are able to normalise cholesterol by attenuating its efflux. Skeletal muscle lacks the cholesterol homeostatic mechanisms of cardiac muscle and is therefore more susceptible to statin-induced damage by long term cholesterol depletion. The marked decrease in both cholesterol and caveolin, two essential elements of caveolae, in statin-treated skeletal muscle may be a mechanism underlying statin-induced myopathy.

Localization of atrial natriuretic peptide and impact of acute stressors on its expression in rat heart

J. Slavikova[1], M. Chottova Dvorakova[1,2], S. Hynie[2], P. Sida[2], E. Mistrova[1] and V. Klenerova[2]

[1]Department of Physiology, Faculty of Medicine in Plzen Charles University Prague, Plzen, Czech Republic and [2]Institute of Medical Biochemistry, First Faculty in Medicine Charles University Prague, Prague, Czech Republic

Atrial natriuretic peptide (ANP) which is produced by mammalian cardiomyocytes is involved in the regulation of blood pressure and fluid homeostasis. The peptide induces suppression of the renin-angiotensin as well as the sympathetic nervous systems to protect cardiovascular homeostasis, which is also deteriorated by the stress. The present study was designed to detect ANP and to examine expression of ANP mRNA in all heart compartments. Additionally, we investigated whether ANP distribution and ANP mRNA expression in the heart could be affected by the stress. We used male Sprague-Dawley (SD) rats (200g). Treatment of animals was in accordance with the Declaration of Helsinki Guiding Principles on Care and Use of Animals [DHEW Publication, NHI 80-23]. The study was approved by the Ethical Review Committee, First Faculty of Medicine, Charles University in Prague. A restraint stressor (immobilization, IS) and IS combined with partial immersion of rats into water (ICS) were applied to animals for one hour. One or three hours after the stress termination, the rats were decapitated, hearts were removed, and each atrium and ventricle were examined separately. Thus, all studies were performed in five groups of animals: in controls, IS1, IS3, ICS1, and ICS3 (n=4-6 per group). ANP localization in sections of preparations was identified by indirect immunohistochemistry with the use of specific commercial antibody. Expression of ANP mRNA was detected by real-time qRT PCR in all heart chambers by comparing their threshold cycle values (CT) to CT of reference gene β-actin. The relative expression ratios were calculated using Mann-Whitney test. Values are means ± S.E.M. In control rats, ANP-immunopositivity was strongly expressed in the left (LA) and right (RA) atrium in coarse granules within the cytoplasm (n=3 per group). No immunofluorescence was observed in the left (LV) and right (RV) ventricle in both control and stressed animals. ANP mRNA expressions were much higher in atria than in ventricles. In control rats, rank order of the gene expression was: LA = 138.8 (p<0,005) > RA = 39.2 (p<0,005) > RV = 10.1 (p<0,005) > LV = 1. The stress exposition led to increased expression of ANP mRNA by 56% (1.56±0.18, p<0.05) in RA, 22% (1.22±0.09, p<0.05) in LA, and 90% (1.90±0.37, p<0.05) in LV after IS1. The increase was also observed after IS3 in the same compartments, by 53% (1.53±0.14, p<0.05) in RA, 49% (1.49±0.21, p<0.05) in LA, and 134% (2.34±0.20, p<0.05) in LV. Combined stress (ICS3) caused the increase of ANP mRNA expression by 67% (1.67±0.22, p<0.05) in LA and by 187% (2.87±1.0, p<0.05) in LV. In conclusion, restraint stressors induced changes in expression of ANP mRNA in cardiomyocytes of atria and left ventricles; these effects may have relevance to ANP induced cardioprotection.

Ischemia modified albumin: a sensitive and reliable marker of cardioprotection during on-pump cardiac operations

I.Z. Solak Gormus[1], A. Kiyici[2], M. Kayrak[3], N. Gormus[4] and N. Ergene[1]

[1]Physiology, Meram Medical School, Konya, Turkey, [2]Biochemistry, Meram Medical School, Konya, Turkey, [3]Cardiolgy, Meram Medical School, Konya, Turkey and [4]Cardiovascular Surgery, Meram Medical School, Konya, Turkey

Problem statement: The evaluation of myocardial protection during on-pump cardiac operations is of great importance. Creatinin kinase, cardiac troponin I, myoglobin, fatty-acid-binding proteins are well known markers for investigation of ischemia (1). Ischemia modified albumin is a reliable, new marker in cardiac ischemia investigations (2). In our prospective study we would like to investigate of our cardioprotective strategies during on-pump cardiac operations with ischemia modified albumin.
Methods: Fifty patients who needed coronary artery bypass operations according to AHA/ACC guidelines were taken to this study. All of the patients were elective cases and the operations were performed with standard cardiopulmonary bypass technique. During the cardiac arrest cold blood cardioplegia solution was used every 20 minutes (10 ml per kilogram) with antegrade technique through an aortic root cannula. Blood samples were taken before and at the end of operations. Cardiac troponin I, albumin, and ischemia modified albumin were investigated in these samples.
Results: There were no deaths after the cardiac operations. The preoperative and postoperative echocardiographic evaluation of ejection fraction were in normal ranges and there were no significant changes. The ischemia modified albumin levels were significantly increased after the cardiac operations ($p < 0.05$), while cardiac troponin I levels did not show any statistically significant difference. The albumin levels were significantly decreased after the operations.
Conclusions: Ischemia modified albumin is a sensitive and reliable marker of ischemia during on-pump cardiac operations. This marker can be used with all other markers in order to evaluate the optimal cardioprotective strategy.

Demographic data of operations and mean ischemia modified albumin and albumin results.

Mean Cardiopulmonary bypass time	75 min
Mean EF (%)	40
Mean number of vessels revascularized	3
IMA preoperative	0.34
IMA postoperative	0.55
Alb preoperative (g/dl)	3.4
Alb postoperative (g/dl)	2.3

Mapping of repolarisation gradients in the canine left ventricular free wall using myocardial slices

P. Camelliti[1], S. Al-Ayoubi[1], J. Cartledge[1], P. Dias[1], M. Yacoub[1], A. Sridhar[2] and C. Terracciano[1]

[1]National Heart and Lung Institute, Imperial College, London, UK and [2]David Jack Centre for Research and Development, GlaxoSmithKline, Ware, UK

Introduction: Studies on isolated cardiomyocytes and ventricular wedges have shown contradicting data on the presence of transmural repolarization gradients in the left ventricle (LV). Here, we investigate electrophysiological heterogeneities of the canine LV free wall, using myocardial slices.
Methods: Vibratome-cut myocardial slices (300 μm thick) were prepared from transmural LV biopsies (10x10x9 mm; n=4 hearts), tangentially to the wall surface. Multiphoton microscopy was used to visualise muscle fiber orientation. Multi-electrode arrays (60 microelectrodes, total area 4.9x4.9 mm) were used to map electrophysiological parameters. Preparations were paced at cycle lengths (CL) ranging from 1 to 4s. Values are means ± S.E.M.
Results: Slices had longitudinal muscle fiber orientation, independent from transmural location. Activation-recovery intervals (ARI; Fig) correlated with transmural site at all pacing CL ($p<0.001$; ANOVA), with the longest values found in a 1.2 mm layer of the deep midmyocardium (4.8 to 6 mm from the epicardial surface; total LV thickness 9 mm). Longer pacing CL heterogeneously prolonged ARI (Fig) and increased transmural repolarization gradient from 63±7 to 106±3 ms (1s versus 4s CL; $p<0.01$ t-test). In plane ARI dispersion ranged from 9±1 to 18±3 ms, and was independent from transmural location and CL ($p>0.05$; ANOVA), suggesting the presence of electrophysiologically homogeneous and well coupled cells in each slice.
Conclusion: The deep midmyocardium contains a well-defined homogeneous region of prolonged ARI, which may contribute to repolarisation gradients in the canine LV.

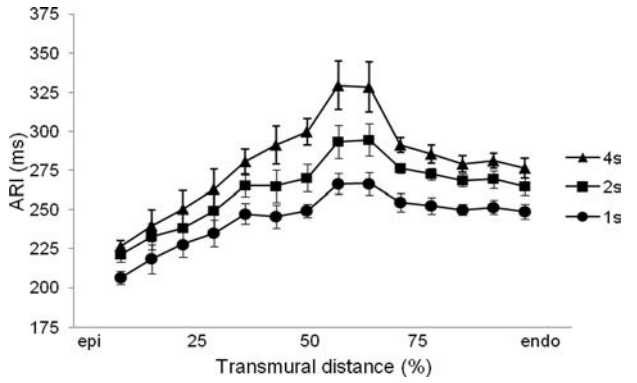

Figure: Transmural activation-recovery interval (ARI) profile measured at pacing CL ranging from 1 to 4s.

Histological and immunohistochemical study of the myocardial sleeves of the extensive pulmonary vein network of the rat

Y. Xiao[1,2], X. Cai[1], A. Atkinson[1], S. Logantha[1], G. Hart[1], M. Boyett[1], Z. Shui[1] and H. Dobrzynski[1]

[1]University of Manchester, Manchester, UK and [2]Cardiovascular Surgery, Union Hospital, Huazhong University of Science and Technology, Wuhan, China

Atrial fibrillation is the most common clinical cardiac arrhythmia and is associated with cardiac dysfunction and stroke. It is believed to be triggered by ectopic electrical activity originating in the myocardial sleeves surrounding the pulmonary veins. Despite their importance, the processes within the pulmonary veins that lead to cardiac arrhythmias are unknown. The aim of this study was to investigate the architecture of the pulmonary veins. Male Sprague-Dawley rats (~450 g) were heparinized and humanely sacrificed in accordance with the UK Animals Scientific Procedures Act 1986. The hearts were perfused with phosphate buffered saline to flush out blood and then embedded in freezing medium and frozen in isopentane cooled in liquid N2. Cryosections of 20 μm thickness were cut in the coronal, sagittal and transverse planes from the whole hearts. From each heart, 16 sections (at intervals of 400 μm) were stained with Masson's trichrome. At levels containing the pulmonary veins, sections were double immunolabelled for connexin43 (major gap junction protein in the working myocardium of the heart; Cx43) and caveolin3 (cardiac-specific isoform of the caveolin family) or alternatively Cx43 and HCN4 (major isoform responsible for the pacemaker current If in nodal tissues). The best view of the pulmonary veins was from sections cut in the transverse plane; it was possible to view the majority of the pulmonary veins in one section. Sections cut in the coronal plane were the best for showing the right superior pulmonary vein, as well as the sinoatrial and atrioventricular nodes. An example of a transverse section through the pulmonary veins immunolabelled for Cx43 and HCN4 is shown in Fig. 1. The marker of cardiac myocytes, caveolin3, was expressed throughout the atria (data not shown). It was also expressed in the myocardial sleeves of the pulmonary vein and its many branches (data not shown). The marker of working myocardium, Cx43, was also expressed throughout the atria (except for the sinoatrial and atrioventricular nodes) as well as the myocardial sleeves of the pulmonary vein and its branches (Fig. 1). In contrast, the nodal marker HCN4 was only expressed in the sinoatrial and atrioventricular nodes; it was not expressed in the working myocardium and it was not expressed at any point in the myocardial sleeves of the pulmonary vein and its branches (Fig. 1). HCN4 is, therefore, unlikely to be responsible for the ectopic activity of the pulmonary veins. In conclusion, it has been shown that the myocardial sleeves of the pulmonary veins can be identified by immunolabelling and the myocardial sleeves extend for many millimetres in the extensive pulmonary vein network of the rat. This is consistent with the work of Logantha et al. (1), who have shown cardiac action potentials can be recorded from intrapulmonary branches of vein.

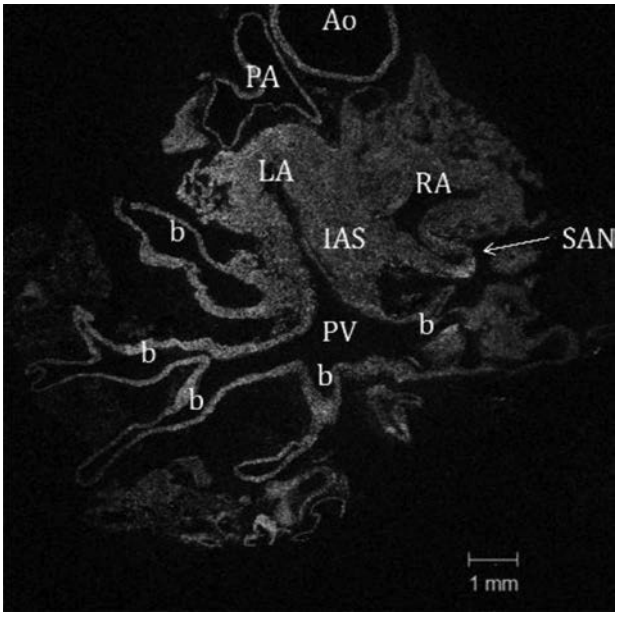

Fig1. Immunolabelling for Cx43 and HCN4 in transverse section at the level of the pulmonary veins. RA, right atrium; LA, left atrium; PV, pulmonary vein; b, branch of pulmonary vein; Ao, aortic artery; PA, pulmonary artery; IAS, interatrial septum; SAN, sinoatrial node.

Steep APD restitution in rat failing right ventricular myocytes

M.E. Hardy[1], O. Bernus[2,1] and E. White[1]

[1]School of Biomedical Sciences, University of Leeds, Leeds, UK and [2]Inserm U-1045 Universite de Bordeaux 2, Bordeaux, France

Pulmonary artery hypertension causes the right ventricle (RV) to become hypertrophied and fail. During this process the RV undergoes electrophysiological remodeling with resultant changes in action potential duration (APD). This study evaluated the effects of removing intracellular calcium (thus preventing forward-mode sodium-calcium exchanger (NCX) current) on the altered APD restitution in hypertrophied RV rat myocytes. Additionally experiments were performed using

ranolazine to assess the effects of the late sodium current ($I_{Na,late}$) on APD restitution in these cells.
Male Wistar rats were given a single i.p. injection of monocrotaline (60 mg/kg) or an equivalent volume of saline. When clinical symptoms of heart failure became apparent (3-4 weeks later) animals were euthanized and the hearts excised. RV myocytes were enzymatically isolated and used for measurements of APD at pacing rates between 1 and 9 Hz. Both sham and failing cells were either left untreated, loaded with BAPTA-AM (5 μM for 15 min), or perfused with 5 μM ranolazine. Some cells treated with BAPTA were also used under discontinuous (4 kHz) action potential (AP) clamp to impose the AP recorded at 1 Hz at pacing rates of 1, 2, 5 and 7 Hz.
Myocytes from the failing RV had a steeper APD_{90} restitution curve and significantly longer APD between 1 and 9 Hz compared to sham cells at all pacing rates ($p < 0.01 – 0.0001$, 2 Way ANOVA, Tukeys post-test, n = 5-6 cells). Despite this greater APD shortening, under AP clamp, compensation currents in failing myocytes were smaller in amplitude as pacing frequency increased (at 7 Hz, $p < 0.05 – 0.0001$ at -40 to 0 mV, n = 5-7). However, integrating the currents showed that in failing cells (which had a longer APD), greater positive charge was passed ($p < 0.05 – 0.0001$ at -40 to -25 mV, n = 3-7).
Failing RV cells that were preloaded with BAPTA had no significant change in APD_{90}. However, at APD_{25}, BAPTA increased the gradient of the restitution curve causing significant increases in duration at slower pacing frequencies ($p < 0.05 – 0.001$ at 1-2 Hz, n = 5 cells). Under AP clamp, BAPTA caused increases in positive charge passed at more positive membrane potentials, compared to untreated hypertrophied cells.
Inhibition of $I_{Na,late}$ using 5 μM ranolazine had no effect on either the APD_{90} or APD_{25} in either sham or failing RV myocytes (n = 6-9).
These data show that cells isolated from the monocrotaline treated RV have a longer APD and steeper APD restitution than those from sham animals. Additionally, our results suggest that steeper APD restitution in failing RV myocytes is not caused by either forward mode NCX or $I_{Na,late}$. Steeper restitution with decreased currents recorded under AP clamp is consistent with an increase in membrane resistance in failing cells. This may be caused by downregulation of K^+ currents. We are currently investigating this possibility.

PCA078

Functional characterization of stem cell-derived cardiomyocytes: a comparative study

I.C. Marcu[1], P. Heuking[2], M. Jaconi[2] and N.D. Ullrich[1]

[1]Department of Physiology, University of Bern, Bern, Switzerland and [2]Department of Pathology and Immunology, University of Geneva, Geneva, Switzerland

Cardiovascular diseases represent the number one cause of death globally, and high prevalence of atherosclerosis in coronary vessels is paving the way for the development of ischemic heart disease and myocardial infarction. The low regenerative potential of the human heart cannot prevent the detrimental remodelling after cardiac injury, and therefore, the use of stem cells (SCs) for cardiac repair has gained great interest in recent years. In spite of ongoing preclinical and clinical trials using SCs in the heart, only little is known about the basic functional properties of these newly generated heart cells, and recent advances in reprogrammation of somatic cells into cardiomyocytes add to the need of thorough characterization of these cells, before functional integration of these cells into the myocardium can be advised.
The aim of this study was to characterize the electrical properties of SC-derived cardiomyocytes of different sources and to investigate intercellular coupling between cell pairs. For our comparison, we used mouse embryonic and induced pluripotent SC-derived cardiomyocytes (ESCs, iPSCs) and assessed their function relative to native neonatal cardiomyocytes and cultured HL-1 cells.
Parallel electrophysiological measurements using the patch clamp technique and confocal Ca2+ imaging with fluo-3 allowed us to study electrical parameters of the cells and excitation-contraction coupling. In order to study intercellular communication between neighboured myocytes, expression of gap junction proteins was confirmed in immunocytochemical assays and the gap junction permeant fluorescent dye calcein was used to measure metabolic coupling between cells.
In differentiated SC-cardiomyocytes, we have identified two distinct populations of cardiomyocytes, spontaneously active and silent but excitable cells, as reflected by the shape of their action potentials. They functionally express the pacemaking HCN channel in spontaneously active cells and cardiac-specific voltage-dependent Na+, L- and T-type Ca2+ channels, as confirmed by current properties and pharmacology. Immunocytological examination revealed strong expression of the cardiac gap junction protein connexin-43. Functional tests of intercellular coupling confirmed electrical coupling between SC-cardiomyocytes. However, permeation kinetics of dye transfer in SC-cardiomyocytes were similar to HL-1 cells, but significantly reduced in comparison with neonatal cells.
In conclusion, we provide a clear physiological profile of single and coupled SC-cardiomyocytes of different origin and evaluate their functional similarities with native cardiomyocytes and HL-1 cells. Despite strong electrophysiological parallels, the disparities in metabolic communication need to be carefully considered for future use of these cells in cardiac regenerative therapy.

PCA079

An investigation into the effects of single point mutations found in patients with hypertrophic cardiomyopathy upon Junctophilin-2 structure and stability

H. Bennett, B. Davenport, A.W. Trafford, C. Pinali and A. Kitmitto

Faculty of Medical and Human Sciences, The University of Manchester, Manchester, UK

Excitation contraction coupling in cardiac muscle requires a precise spatial organisation of the L-type voltage-gated calcium channel (LTCC), on the t-tubule (t-t) membrane, and the ryanodine receptor (RyR2) localised to the junctional sarcoplasmic reticulum (jSR)[1]. In the heart, Junctophilin-2 (JP2) is thought to act as a scaffold to bridge, and stabilise, the gap between the two membranes forming the dyadic cleft. JP2 is believed to be tethered to the SR, via a C-terminal transmem-

brane domain, span the cytosol, and bind to the inner leaflet of the t-t via the N-terminal region. Genetic defects in JP2 have been associated with hypertrophic cardiomyopathy (HCM), which is the most common cause of sudden cardiac death in young people[2]. Several single amino acid mutations have been discovered within JP2 in HCM patients (S101R, S165F, Y141H, G505S) significantly, these carriers did not have any mutations of the Z-disc or contractile proteins typically associated with HCM[3]. The mechanisms by which these mutations lead to disease are still not understood. In order to investigate how the introduction of single point mutations influence the function of JP2 we have expressed and purified wild-type and mutant JP2 proteins from *E. coli*. Using fluorescence spectroscopy, exploiting the presence of instrinsic tryptophan residues within the JP2 amino acid sequence, we examined the thermal denaturation profiles of each protein. Slit widths were set at 5 nm, the excitation wavelength at 280 nm and the emission collected at 280 nm, 330 nm and 350 nm. The temperature was increased at a rate of 0.5ºC min^{-1} (20 - 80ºC). The transition temperature (T_m), the temperature at which 50% of the protein is denatured, was determined for wild-type and mutant JP2 by plotting the ratio of the emission intensity F_{330}/F_{350}. Guanidine hydrochloride was employed to study the effects of chemical denaturation and secondary structure analysis was conducted using circular dichroism (CD). Thermal and chemical denaturation experiments revealed the mutations had no overall effect on protein stability and the T_m for each protein was 52ºC. CD revealed that JP2 is comprised of 38% α-helix, 16% β-sheet, 18% turns and 28% random coil, correlating with predicted secondary structure analysis. However, the S101R and Y141H mutants exhibited changes to the secondary structure profile with a reduction to the overall helical content and increase in random coil. These results indicate the JP2 mutations do not appear to effect the stability of the protein but lead to a modification of the structure which may alter the t-t binding properties and/or disrupt potential protein interactions between JP2 and dyadic cleft proteins involved in calcium homeostasis.

Increased cytosolic [Na] despite increased sodium potassium pump activity during early development of heart failure in beta1 adrenergic receptor overexpressing mice

P. Schoenleitner[1], G. Antoons[1], S. Khan[1], G.J. Unterer[1], P. Wakula[2], S. Engelhardt[3], B. Pieske[2,1] and F.R. Heinzel[2,1]

[1]Cardiology, Medical University Graz, Graz, Austria, [2]Ludwig Boltzmann Institute for Translational Heart Failure Research, Graz, Austria and [3]Pharmacology&Toxicology, Technische Universitaet Muenchen, München, Germany

Chronic stimulation of the β1-adrenergic pathway leads to cardiac hypertrophy and heart failure (HF). In mice overexpressing the β1-adrenergic receptor (β1), changes in Ca2+ handling precede the development of structural hypertrophy at an early stage of remodelling (8-12w). The Na+/K+ ATPase (NKA) is an important regulator of [Na+]i, and indirectly of Ca2+ homeostasis. Therefore we investigated putative changes in NKA activity, regulation and expression as well as mechanisms linked to the regulation of Na+ and Ca2+ in an early stage of HF.

Single left ventricular myocytes were isolated from 8-12 weeks old male β1 mice and wild-type littermates (WT). For Na+-measurements, myocytes were loaded with SBFI-AM. Relaxation of Ca2+ transients (CaT, fluo-3 AM) was measured as the time constant of decay by exponential fitting (time constant tauStim for CaT during 0.5Hz stimulation; and tauCaff for caffeine-induced transients, 20 mM). For NKA pump current measurements (Ip) a Cs-Asp based pipette solution with 10 mM Na+ was used. To measure maximal Ip, Cs-Asp was replaced with Na-Asp to a final concentration of 100 mM [Na+]pip. Cells were superfused with normal Tyrode solution with additional, in mM: 2 BaCl2, 2 NiCl2 (pH=7.4 with NaOH), at 37°C. Ip was measured as the difference in outward current, at 0 mV, after rapid solution switch to K+-free solution. Currents were normalized to cell capacitance. Protein expression of NKA subunit α1 and α2, NHE 1, TRPC 1/3/6, PLM and PLM phosphorylation were determined using Western blotting in whole ventricle homogenates. Protein densities were normalized to GAPDH.

In β1 myocytes, CaT showed a slower decline (tauStim 232±27ms in β1 vs. 180±17 ms in WT;mean±S.E.;n≥11/group;P<0.05). Ca2+ removal via forward NCX was significantly slowed. Cytosolic [Na+] was increased in resting cells (24.3±4.5 vs. 14.2±2.5 mM), and during stimulation (1Hz: 27.6±5.1 vs. 17.6±3.5 mM; 3 Hz:28.6±5.4 vs. 19.7±4.4 mM;n=14 and 8 respectively; all P<0.05). Protein levels of the NKA α1 subunit, NHE 1, TRPC 1,3 and 6 were unchanged, whereas the α2 subunit was reduced. Phospholemman (PLM), an inhibitory subunit of NKA, showed increased phosphorylation at Ser68 and the total amount was reduced in β1 mice. With [Na+]pip=10 mM, Ip density was significantly increased in β1 myocytes. Maximal Ip density was unchanged. In β1 mice, the slower Ca2+ removal via NCX is related to increased cytosolic [Na+]i.

Proteins related to Na+ influx, NHE 1, TRPC 1/3 and 6, are not differentially regulated at this early stage of cardiac remodeling. At physiological [Na+]i, NKA current is increased, consistent with the higher phosphorylation degree of PLM, thus rather acting as a compensatory mechanism for the high Na+ levels during early remodeling in heart failure.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Conduction defects and fibrosis in aged hearts with long QT syndrome 3

F. Syeda[1], D. Kucerova[2], I. Piccini[2], L. Fortmueller[2], G. Riley[1], M. Schaefers[3], M. Kuhlman[3], P. Kirchhof[1,2] and L. Fabritz[1,2]

[1]University of Birmingham, Birmingham, UK, [2]University Hospital Muenster, Muenster, Germany and [3]European Institute for Molecular Imaging, Muenster, Germany

Background and objectives: Altered sodium channel expression and function can cause sudden death. A knock-in mouse model with increased late sodium current, mimicking long QT syndrome 3 (δ-KPQ-SCN5A), was used to study effects of ageing on ventricle-ventricle conduction.

Methods: Electrophysiology-Hearts were removed from δ-KPQ-SCN5A (dKPQ) and their wildtype (WT) littermates under terminal anaesthesia with urethane (2mg/kg), and immediately perfused on a modified upright Langendorff apparatus, where monophasic action potentials were recorded using custom-made Ag-AgCl electrodes. Interventricular activation times were measured during right ventricular pacing at 100ms fixed-rate cycle length, in three age groups (very young: 2-5 months, young: 6-9 months, and old: 18-24 months).
Histology- 4μm-thick sections of paraffin-embedded hearts were stained with picrosirius red/haematoxylin. Collagen deposition was quantified using NIS Elements imaging software (Nikon) and Image J (National Institutes of Health, USA). Fibrosis was expressed as % of connective tissue relative to the total tissue inside the region of interest.
Results: In old WT mice (18-24 months) there was no significant increase in activation time, compared with very young mice (2-5 months, 11±1, n=11 vs. 13±1, n=8). Conduction times were consistently longer in dKPQ mice in older mice (very young: 11±1, n= 11 vs. 13±1, n=8; young: 10±1, n= 7 vs. 16±1, n=7*; old: 13±1, n= 8 vs. 17±1, n=9*). Consistent with the subtle conduction defect, there was subtle ventricular fibrosis in old dKPQ hearts and upregulation of several genes involved in fibrosis and structural remodelling, compared with old WT hearts.
Conclusion: A selective increase of the late sodium current may adversely affect ventricular conduction and this may be linked with ventricular fibrosis.
All values are expressed as mean±SEM, *p<0.05.

Life with "arrhythmia": peculiarity of pacemakering in ascidia's heart myoepithelial cells

V. Golovko and M. Gonotkov

Institute of Physiology, Syktyvkar, Russian Federation

Despite the considerable interest and a big amount of studies on various aspects of the electrophysiology of cells that initiation heart rhythm, the understanding of the mechanisms underlying their electrogenesis is insufficient. The main goal of this work is to analyze the effects of blockers of K +, Na + and Ca2 + channels on the configuration of the phases of the action potential and to determine which of the currents is pivotal. Method. The experiments were performed on spontaneously contracting heart of ascidia Styela rustica (n = 13) using microelectrode technique. Isolated heart was perfused with aerated sea (White See) water (mmol): 280 NaCl; 6 KCl; 36 MgCl2; 7 CaCl2; 19 Na2SO4; pH ~ 8.1 (Kuzmin et al., 2012).
Results. Action potentials of the myoepithelial cells in the heart were divided into two types: the action potential with slow diastolic depolarization (SDD; pacemaker) and without diastolic depolarization (working or contractile). Cells without SDD generated AP with a higher amplitude 96 ± 11 mV, and dV / dtmax 7 ± 1 V / sec (n = 12) comparing to the pacemaker type cells 71 ± 6 mV and 1.6 ± 0.3 V / sec (n = 4). All ascidia heart cells exhibited as episodes with burst from 7-16 action potentials. Then there was a pause for about a minute, after which there was a burst of APs on the other, turned to the stomach, side of the heart. On average, the frequency of action potential generation was 11 ± 4 pulses per min, without counting the time of "silence" or pause. Lidocaine (1 mM) decreased the dV / dt max in the contractile cells from 4.9 ± 0.3 V / sec up to 3.7 ± 0.4 V / sec (n = 5; 21%), and lengthed prolonged the action potential at 20 % of repolarization, APD 20 from 75 to 120 ms compared to the control . In pacemaker cells 4-aminopyridine (4AP; 5 mM) increased APD20 three times and decreased the upstroke velocity dV / dt max by more than 50% compared with the control. The period of the action potential generation in this burst did not changed. The increasing of the amount of APs in bursts, the decrease of the time of pauses in two-three times, the increasing of action potentials duration at 90 % of repolarization by 51% compared to the control were registered after the 30 minutes exposure to EGTA (5 mM).
The data indicate that K-currents play a pivotal role in the generation of pacemakering of ascidia's heart myoepithelial cells.

PCA085

Unambiguous rapid sarcomere length measurements using remote focussing microscopy

R.B. Burton[1], A. Corbett[2], E.J. Botcherby[2], C.W. Smith[2], C. Bollensdorff[3], T. Wilson[2], M. Booth[2] and G. Bub[1]

[1]Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK, [2]Department of Engineering Science, University of Oxford, Oxford, UK and [3]National Heart and Lung Institute, Imperial College London, London, UK

Introduction: Sarcomere length (SL) is an important indicator of cardiac mechanical function, but current imaging modalities cannot unambiguously measure and characterize SL at the cell level in intact, living tissue(1). We have developed a method for measuring SL and tissue orientation using remote focusing microscopy, an emerging imaging modality that can capture 2-photon fluorescence from oblique planes.
Methods: The illumination spot in a microscope can be translated along the z-axis by illuminating the objective lens with a non-parallel light beam, however this introduces significant optical aberrations. To obtain diffraction-limited performance and fast z-scanning, we use an axial scan unit (ASU) consisting of a second, matched objective that compensates for aberrations introduced by the imaging objective and a lightweight mirror. We have demonstrated that rates of up to 2.7 kHz are achievable with our system, due to the low weight of our scanning mirror. The scan speed in the z-direction is therefore comparable with galvanometer scan rates in the xy-plane(2).
All experiments conformed to the Guide for the Care and Use of Laboratory Animals published by the Animals (Scientific Procedures) Act 1986 (UK). Hearts were isolated from female Sprague-Dawley rats, swiftly perfused via the aorta in Langendorff mode, loaded with membrane dye di-4-ANEPPS, transferred to a custom built cradle and imaged. We measure cell orientation from user selected cells in a field of view by imaging sarcomere structure on two oblique sub-planes that share a common major axis with the cell, at +45° and -45° to the image plane.
Results: Our methods captured a wide range of tissue angles, ranging from 0 to 26 degrees over 8 experiments. SL correction using the angle data calculated from the arbitrary planes resulted in an average reduction of SL standard deviation of

7%, and in one experiment the standard deviation for SLs decreases from 0.071 μm to 0.055 μm after correction, a 23% reduction.
Discussion: Remote focusing microscopy can unambiguously measure cell orientation in complex two photon data sets without capturing full z-stacks. The techniques presented here will allow rapid assessment of SL in healthy and diseased heart experimental preparations.

Individual microvascular units are critical to cardiac performance

S. Egginton[1,2], D. Hauton[1,3], J. Winter[1,4], A. Al Shammari[5], E. Gaffney[5] and R. Evans[6]

[1]Physiology, University of Birmingham, Birmingham, UK, [2]Biomedical Sciences, University of Leeds, Leeds, UK, [3]Applied Medicine, University of Aberdeen, Aberdeen, UK, [4]Cardiovascular Sciences, University of Leicester, Leicester, UK, [5]Mathematical Institute, University of Oxford, Oxford, UK and [6]Physiology, Anatomy & Genetics, University of Oxford, Oxford, UK

High cardiac energy demand relies on lipid & glucose oxidation, depending on oxygen availability [1]. The relative importance of functional capillary supply or ability to switch between substrates to preserve cardiac performance is currently unclear, but may be critically important in conditions such as diabetes that are characterized by a reduced metabolic flexibility through the loss of insulin sensitivity [2]. The role of arteriole perfusion in selection of substrates was established before and after infusion of polystyrene microspheres (mean diameter 15.0±0.2μm) to mimic capillary rarefaction due to microvascular disease. The effect of acute loss of functional capillary supply on palmitate and glucose metabolism together with function was determined in normal working hearts from male rats. Random blockade of coronary arterioles by microspheres decreased rate-pressure product (RPP; R^2=0.82) in a dose-dependent manner, and halved peak developed pressure (P<0.01), in perfused-working hearts [3] from control and STZ-diabetic rats. Palmitate oxidation halved (P<0.001) with a similar increase in glucose oxidation (P<0.01) for control hearts, but in diabetic hearts palmitate oxidation was 2.5-fold higher (P<0.001) with unchanged glucose oxidation (ns). Arteriole occlusion decreased the density of patent capillaries by 40% (P<0.001) and increased capillary supply area by 60% (P<0.01). There was a more heterogeneous distribution of functional capillaries in the myocardium following microsphere infusion (CV=19.15% untreated vs. 25.80% occluded). Calculated myocardial PO^2 was sensitive to occlusion of arterioles leading to a decrease in oxygen consumption, and an increase in the fractional area of hypoxic regions. Graded loss of arteriole supply thus led to a reduction in both coronary flow and cardiac work, and metabolism was also decreased as a consequence. Interestingly, hearts demonstrate the capacity to switch between substrates, from palmitate to glucose, to maximise oxygen efficiency and sustain cardiac work. Our data suggests that the decline in performance noted for the heart in chronic diabetes may not be metabolic in origin but could result from the secondary consequence of diabetes, namely capillary rarefaction and microvascular disease leading to a regional inadequacy in oxygenation of the myocardium. This supports the importance of preventing arteriole loss as a consequence of microvascular disease.

Effects of cannabinoid-1 receptor blockade in diabetic cardiomyopathy

S. Batkai[1], M. Rajesh[2], P. Mukhopadhyay[2], B. Horvath[2], R. Cinar[2], L. Liaudet[3], K. Mackie[4], G. Hasko[5] and P. Pacher[2]

[1]IMTTS, Hannover Medical School, Hannover, Germany, [2]NIAAA, NIH, Bethesda, MD, USA, [3]Department of Intensive Care Medicine, University Hospital, Lausanne, Switzerland, [4]Department of Psychological and Brain Sciences, Indiana University, Bloomington, IN, USA and [5]Department of Surgery, University of Medicine and Dentistry of New Jersey, Newark, NJ, USA

Diabetic cardiomyopathy is characterized by left ventricular hypertrophy, early diastolic dysfunction and/or systolic dysfunction that leads to heart failure in diabetic paients. The endocannabinoid system has a recognized role in the development of various cardiac diseases due to involvement in cardiac dysfunction, inflammation, fibrosis and cell death.
In this study, the role of cardiac CB1 receptor signaling was explored in a stertozotocin-induced type 1 diabetic mouse model. The animals with chronically increased blood glucose levels developed characteristic diabetic cardiomyopathy assessed by intraventricular pressure-volume catheter system. At the tissue level, the hearts after 12 weeks of diabetes showed increased myocardial oxidative/nitrative stress, p38/Jun kinase (JNK) and mitogen-activated protein kinases (MAPKs) activation, enhanced inflammation and fibrosis, accumulation of advanced glycation end product (AGE), increased AGE and angiotensin II type 1 (AT1R) receptors, decreased expression of sarcoplasmic/endoplasmic reticulum Ca2+-ATPase (SERCA2a). Overactivation of the endocannabinoid system due to the diabetes was evident by increased cardiac endocannabinoid anandamide levels and cannabinoid 1 (CB1) receptor expression. Pharmacological inhibition or genetic deletion of the CB1 receptors attenuated the diabetes-induced cellular alterations and improved cardiac dysfunction. Most importantly, pharmacological inhibition of CB1 receptors may preserve its beneficial effects on contractile dysfunction even if administered after the development of established cardiomyopathy.
Overactivation of cardiac CB1 receptors by endocannabinoids may play an important role in the pathogenesis of diabetic cardiomyopathy by facilitating various intracellular signaling

(MAPK activation, AT1R expression/signaling, AGE accumulation, oxidative/nitrative stress), inflammation, and fibrosis. Conversely, pharmacological inhibition of cardiac CB1 receptor may be beneficial in the treatment of diabetic cardiovascular complications.

A new index for evaluating the strength of left ventricular vortex: in silico study

E. Shim[1], C. Leem[2] and Y. Earm[3]

[1]Kangwon National University, Chuncheon, Republic of Korea, [2]University of Ulsan, Seoul, Republic of Korea and [3]Seoul National University, Seoul, Republic of Korea

Left ventricular vortex plays a critical role in blood ejection from left ventricle (LV) to aorta. In spite of several parameters for evaluating LV vortex, there still remain fundamental questions to categorize LV vortex. Here, we propose the Reynolds number (Re), based on mitral valvular velocity and diameter, as an evaluation index for LV vortex strength and verify this by using a computational method. For this purpose, we implement an integrative model of heart and blood flow simulating sequential events of heart from cellular electric excitation-contraction to 3D tissue contraction, and eventually blood hemodynamics in LV. Simulation of fluid structure interation (FSI) in this study couples cardiac electromechanical model presented in our previous study [1] with the code of computational fluid dyanamics [2]. Remeshing algorithm is used to account for the mesh vairtion according to vave and ventricular wall motions. First, we verify the present method by comparing computed results with clinical observations. Then, we investigate the effect of Re variation on the strength LV vortex. Simulated results show that the strength LV vortex can be classified by Re, indicating Re is a useful index for diagonizing hemodynamic dysfunction of LV.

Gestational intermittent hypoxia induces sex-differential DNA methylation of corticotropin-releasing hormone receptor 1 associated with anxiety-like behavior in rat offspring

X. Wang[1], F. Meng[1], Z. Liu[2], J. Fan[1], K. Hao[1], X. Chen[1,2] and J. Du[1,3]

[1]Neurobiology and Physiology, Zhejiang University, Hangzhou, China, [2]Key Laboratory of Medical Neurobiology of the Ministry of Health, Hangzhou, 310058, China and [3]Zhejiang Province Key Laboratory for Neurobiology, Hangzhou, 310058, China

Early life stress in gestation may result in an increased vulnerability to disease and behavior alteration in offspring. The fetus may often experience intermittent intrauterine hypoxia stress under a variety of conditions, such as pregnancy at high altitude, pregnancy with anemia, cord compression, hypertension, obstructive sleep apnea and preeclampsia. The mechanism regarding the fetal antecedents contributing to disease development remains limited. Here we reported that maternal gestational intermittent hypoxia (GIH) induced by hypobaric high-altitude hypoxia of 5km (equivalent to ~10.8% O2 at sea level), 4 hour / day for 21 days caused a sex-dependent anxiety-like behavior in 90-day-old (P90) male offspring but not female offspring analyzed by open-field test, light-dark box test and elevated plus maze test (n=10, $p<0.05$). The *CRHR1* mRNA expression in PVN and central amygdala (CeA) of P90 (n=8) and in hypothalamus of embryonic day 19 (E19) (n=7) were tested by quantitative real-time PCR. We found that there was a significant increase of *CRHR1* mRNA expression in male's PVN ($p<0.05$) but not in female's at the age of P90. No difference of *CRHR1* mRNA expression was found in CeA of P90 offspring. GIH also induced an increased *CRHR1* mRNA in the hypothalamus at the E19 ($p<0.05$). There were two CpG (island-1 and -2) within the *Crhr1* gene promoter by the software analysis, and we demonstrated the island-1 between -607 and -502 bp functioned as the major regulatory domain of *Crhr1* transcription activity, and found that the demethylation at the CpG sites of *Crhr1* promoter enhanced *CRHR1* mRNA expression *in vitro* (n=3, $p<0.001$). Furthermore, *in vivo*, the increase of *CRHR1* mRNA expression might be modulated by the decreased methylation at -535 CpG sites within the island-1 occurred in male E19 embryo (n=7, $p<0.05$) and the other in CpG three sites, such as -587 ($p<0.01$), -547 ($p<0.05$) and -544 ($p<0.01$) in the PVN of P90 male offspring (n=10), which might come from a decreased expression of DNMT3b in male offspring after GIH (n=7, $p<0.05$). In conclusion, GIH induces anxiety-like behavior in male adult offspring, which associated with the sex-dependent expression of *CRHR1* mRNA in the PVN but not in the CeA in offspring. GIH can alter *Crhr1* gene methylation, principally via DNMT3b, and *Crhr1* demethylation is associated with high-expressed *CRHR1* mRNA, suggesting a sex-biased mechanism for *Crhr1* gene expression associated with the anxiety-like behavior in GIH adult offspring. Our findings suggest that the vulnerability to hypoxia-induced anxiety in offspring occurs through the sexually differential epigenetic modification of *Crhr1* genomic regions. We address a novel hypothesis, that GIH-induced male-sexdependent demethylation at CpG sites of *Crhr1* DNA in promoter triggers elevation of *CRHR1* mRNA in PVN and anxiety-like behavior in adult offspring.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA091

Codon 104 variation of p53 gene is necessary for enhancing cellular survival strategy in mammals of the Tibet plateau

Y. Zhao[1,2], M. Wang[1,2], X. Chen[2,3] and J. Du[1,2]

[1]Neurobiology and Physiology, Zhejiang University, Hangzhou, China, [2]Key Laboratory of Medical Neurobiology of the Ministry of Health, Hangzhou, China and [3]Key Laboratory of Neuroscience of Zhejiang Province, Hangzhou, 310058, China

While p53 levels and mutations correlate well with tumorigenesis, relatively little is known about the role of p53 variations in environmental adaptation. *Myospalax baileyi* and *Microtus oeconomus*, are native rodents living at the Qinghai-Tibet plateau and well acclimatized to hypoxia, cold, and/or high CO2 environments. The CDS of p53 from *M. baileyi* and *M. oeconomus* were cloned and sequenced. Evolutionary analysis distinguished the codon 104 variation from other sites as an important mutation correlated with the adaptation of these two rodents to plateau environments. The S104N of *M. baileyi* p53 is different from two of its close species *Myospalax cansus* and *Spalax judaei* living at lowland. The S104E of *M. oeconomus* p53 shared with only four fishes and squid, most of which were reported to be hypoxia-tolerant. To address the functional characteristics of their p53, the p53-null human non-small lung cancer cells NCI-H1299 (ATCC CRL-5803) were transfected with expression plasmids of *M. baileyi*, *M. oeconomus* and human p53. As determined by dual-luciferase assays, while the S104N of *M. baileyi* p53 induced stronger transactivation of pro-apoptotic target genes IGFBP3 and Apaf1 (1.9 and 1.5 folds, respectively; $p < 0.001$), the S104E of *M. oeconomus* p53 was responsible for the deficient transactivation of IGFBP3, Apaf1 and bax (0.3, 0.4 and 0.5 folds, respectively; $p < 0.001$). Values are means ± SD, compared by one-way ANOVA (n = 3). Using site-directed mutagenesis and dual-luciferase assays, we demonstrated that the codon 104 variation contributes to its sensitivity to cold and acidic stresses. While *M. baileyi* wt p53 induced IGFBP3 transactivation at 37 °C is 1.5 folds higher than that at 30 °C ($p < 0.001$), both N104S and N104E mutants had similar transactivation to IGFBP3 between 30 °C and 37 °C ($p > 0.05$). At pH 6.0, IGFBP3 induced by *M. baileyi* wt p53 decreased by 40% compared with at pH 7.4 ($p < 0.01$), whereas IGFBP3 induced by N104E mutant only decreased by 10% ($p < 0.05$). We propose that these p53 codon 104 variations are an outcome of environmental adaptation and evolutionary selection that enhances cellular survival strategies befitting the hypoxic, cold, and high CO2 (for *M. baileyi*) environments at the Qinghai-Tibet plateau.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA092

Cellular Localisation and Functions of the ACE2 Metabolite of (Pyr^1)apelin-13

P. Yang, R.E. Kuc, J.J. Maguire, A.L. Brame, N.W. Morrell and A.P. Davenport

Department of Medicine, University of Cambridge, Cambridge, UK

Introduction: Apelin is the endogenous ligand of the G protein-coupled receptor APJ. In human cardiovascular tissues apelin produces endothelium-dependent vasodilatation and positive inotropy *in vitro*, and (Pyr^1)apelin-13 is the predominant isoform of mature apelin in the heart[(1)]. Beneficial roles for both apelin and ACE2, that converts angiotensin-II to angiotensin(1-7), have been reported in pulmonary arterial hypertension (PAH)[(2,3,4)]. Intriguingly, ACE2 also removes the C terminal phenylalanine from (Pyr^1)apelin-13, generating (Pyr^1)apelin-13$_{(1\text{-}12)}$[(5)].

Aims and Hypotheses: Our aim was to investigate whether (Pyr^1)apelin-13$_{(1\text{-}12)}$ is present endogenously in normal and PAH rat and human cardiopulmonary tissues, and to test our hypothesis that this metabolite retains significant biological activity.

Methods: Specific (Pyr^1)apelin-13$_{(1\text{-}12)}$ and ACE2 antibodies were used in peroxidase-anti-peroxidase and dual-labelling fluorescent immunocytochemistry experiments. 30μm sections of cardiopulmonary tissues were from normal and PAH human heart and lung (n=4 for each) and from healthy male Sprague-Dawley rats and rats treated with monocrotaline (60mg/kg s.c.), as a model of PAH (n=4 for each). Biological activity of (Pyr^1)apelin-13$_{(1\text{-}12)}$ was determined in β-arrestin recruitment and receptor internalisation assays, and compared to (Pyr^1)apelin-13 (10^{-11}-10^{-6}M ; n=3-12). Values of pD_2 (negative log10 of the concentration producing 50% of maximum response) and maximum responses were determined using GraphPad Prism.

Results: In both rat and human tissues, (Pyr^1)apelin-13$_{(1\text{-}12)}$-like immunoreactivity(-LI) was present in the endothelium of normal heart and lung and PAH heart and co-localized with ACE2-LI, but was reduced or absent in PAH lung from both species. Furthermore, (Pyr^1)apelin-13$_{(1\text{-}12)}$ exhibited full agonist activity with 5-10 fold lower potency in β-arrestin recruitment (pD_2= 7.84±0.07) and receptor internalisation assays (pD_2= 8.39±0.01) compared to (Pyr^1)apelin-13 (pD_2= 8.76±0.09, pD_2= 8.82±0.01, respectively).

Conclusions: This study demonstrates for the first time that (Pyr^1)apelin-13$_{(1\text{-}12)}$ can be detected in rat and human cardiopulmonary tissues and is present in cells that also express ACE2. Our functional data suggest that ACE2 does not inactivate (Pyr^1)apelin-13, rather the metabolite retains a biological activity comparable to the parent peptide. If the apelin system is beneficial in PAH, it is possible that the observed reduction in (Pyr^1)apelin-13$_{(1\text{-}12)}$ expression in PAH lung may contribute to the pathogenesis of the disease, and generation of (Pyr^1)apelin-13$_{(1\text{-}12)}$ may therefore also contribute to the positive actions of ACE2 therapies.

Delivery of Oct4 and SirT1 genes into aged retinal pigment epithelium by cationinc PEI-polyurethanes

J. Cherng

Biochemistry & Chemistry, National Chung Cheng University, Chia-Yi, Taiwan

SirT1, a NAD-dependent histone deacetylase, is an essential mediator of cellular longevity. Oct4, a POU-domain transcription factor, is highly expressed in maintaining pluri-potency and cellular reprogramming process in stem cells. Both Oct4 and SirT1 (Oct4/SirT1) expression was decreased in an age-dependent manner in retina and retinal pigment epithelium cells (RPEs). Cationic polyurethane, a biodegradable non-viral vector, protects DNA from nuclease degradation and helps to deliver genes efficiently. In this study, polyurethane-short branch polyethylenimine (PU-PEI) was used to deliver Oct4/SirT1 into aged RPEs (aRPEs) or light-injured rat retinas. Rats were anesthetized with intramuscular injections of an equal-volume mixture of 2% lidocaine (0.15 mL/kg) and ketamine (50 mg/mL). The light-injured retinas were confirmed with H&E staining and quantified with the changes in the outer nuclear layer (ONL) thickness. The results showed that Oct4/SirT1 overexpression increased the expression of several progenitor-related genes and the self-renewal ability of aRPEs. Moreover, Oct4/SirT1 overexpression resulted in the demethylation of the Oct4 promoter and enhanced the expression of antioxidant enzymes, which was accompanied by a decrease in intracellular ROS production and hydrogen peroxide-induced oxidative stress. Importantly, PU-PEI-mediated Oct4/SirT1 gene transfer rescued retinal cell loss and improved electroretinographic responses in light-injured rat retinas. These data suggest that PU-PEI-mediated delivery of Oct4/SirT1 reprograms aRPEs into a more primitive state and results in cytoprotection by regulating the antioxidative capabilities of these retinal cells.
(Note: all experiments were performed in compliance with the Animal Care and Use Committee guidelines and in accordance with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research)

PCA094

Curcumin protects nigral dopaminergic neurons by iron-chelation in the 6-hydroxydopamine rat model of Parkinson's disease

H. Xu

Qingdao University, Qingdao, China

Curcumin is a plant polyphenolic compound and a major component of spice turmeric (Curcuma longa). It has been reported to possess free radical-scavenging, iron-chelating, and anti-inflammatory properties in different tissues. Our previous study showed that curcumin protects MES23.5 dopaminergic cells from 6-hydroxydopamine (6-OHDA)-induced neurotoxicity in vitro. The present study aimed to explore this neuroprotective effect in the 6-OHDA lesioned rat model of Parkinson's disease in vivo. Wistar rats weighing 200–220 g were given intragastric curcumin for 24 days. 6-OHDA lesioning was conducted on day 4 of curcumin treatment. Dopamine content was assessed by high-performance liquid chromatography with electrochemical detection, tyrosine hydroxylase (TH)-containing neurons by immunohistochemistry, and iron-containing cells by Perls' iron staining. Results showed the dopamine content in the striatum and the number of TH-immunoreactive neurons decreased after 6-OHDA treatment. Curcumin pretreatment reversed these changes. Further studies demonstrated that 6-OHDA treatment increased the number of iron-staining cells, which was dramatically decreased by curcumin pretreatment. This indicates that the protective effects of curcumin against 6-OHDA may be attributable to the iron chelating activity of curcumin to suppress the iron-induced degeneration of nigral dopaminergic neurons.

PCA095

A novel antibody against Aβ sequence 31-35 efficiently neutralizes Aβ1-42-induced impairments in spatial memory and synaptic plasticity in rats

L. Cheng, X. Li, Y. Pan, X. Chen and J. Qi

Physiology, Shanxi Medical University, Taiyuan, Shanxi, China

Although the immunotherapy for Alzheimer's disease (AD) has achieved some exciting results, current immunization strategies with amyloid β-protein (Aβ) and its antibodies are causing serious side effects in AD patients, which is partly due to the damage of physiological amyloid precursor protein. Our previous studies indicated that the sequence 31-35 in Aβ is a shorter active center responsible for the neurotoxicity of Aβ, suggesting a more specific target for AD treatment. The present study, on the basis of making a specific antibody against the sequence 31-35 of Aβ, observed the effects of the anti-Aβ31-35 antibody on the Aβ1-42-induced impairments of spatial learning and memory in rats and investigated its electrophysiological and cellular mechanisms using Morris water maze (MWM), primary neuronal culture and hippocampal field potential recording. Under the anesthesia with 1% carbrital (50 mg/kg, i.p.), a stainless steel cannula was implanted into the right lateral ventricle of Wistar rats (200-300g) for intracerebroventricular (i.c.v.) injection of drug/vehicle. MWM tests consisted of acquisition phase and probe trial. The hippocampal long term potentiation (LTP) was examined by recording field excitatory postsynaptic potentials (fEPSPs) in the CA1 region of rats under anesthesia with ethyl carbamate (1.5 g/kg, i. p.). In primary culture experiments, cell viability, LDH release and cell survival rate were checked. All data were presented as means ± standard error of the mean. The statistical significance was defined as $p<0.05$. The results showed that i.c.v. injection of anti-Aβ31-35 antibody alone did not change the spatial memory ($p>0.05$, n=8), the basal synaptic transmission and hippocampal LTP ($p>0.05$, n=7) of rats. However, pretreatment with the anti-Aβ31-35 antibody dose-

dependently (0.05-5 nmol) decreased the escape latencies in underwater platform test ($p<0.05$ in 0.5 and 5 nmol group, n=8) and increased the swim time and distance elapsed in the target quadrant in probe trial ($p<0.05$, n=8); 5 nmol Anti-Aβ31-35 antibody almost completely reversed the Aβ1-42-induced suppression of in vivo hippocampal LTP ($p<0.01$, n=6); Aβ1-42-induced cytotoxicity in cultured cortical neurons was also inhibited by the antibody ($p<0.05$ or $p<0.01$), with a nearly normal cell viability and a reduced LDH release. These results suggest that 31-35 sequence of Aβ may be a new therapeutic target for AD, and the anti-Aβ31-35 antibody will be probably useful in AD immunotherapy as a novel anti-Aβ antibody candidate.

PCA096

Apolipoprotein E4 disrupts the induction, not the maintenance of hippocampal late-phase long-term potentiation in rats

F. Qiao, X. Gao and J. Qi

Shanxi Medical University, Taiyuan, China

Alzheimer's disease (AD) is a progressive and irreversible neurodegenerative disorder associated with memory loss, cognitive deterioration and weakness of intellectual capacity. Inheritance of the ε4 allele of the apolipoprotein E gene (ApoE4) is a major risk factor for the development of AD. Although the association between ApoE4 and AD is well documented, the effects of ApoE4 on hippocampal synaptic plasticity which related to long-term memory is unknown. In the present study, we recorded in vivo late-phase long-term potentiation (L-LTP) of field excitatory postsynaptic potentials (fEPSPs) in hippocampal CA1 region of rats, and investigated the possible electrophysiological mechanism of ApoE4 in the induction and maintenance of L-LTP. 60 male SD rats (250-350 g) were used. Under anesthesia with urethane (1.5 g/kg i.p.), the L-LTP was induced by three groups of high frequency stimulation (HFS); ApoE4 solution (0.2 μg, n=24; 2 μg, n=12) was injected into the hippocampus 30 min before HFS (pre-HFS injection) or 1 min after HFS (post-HFS injection). Control rats (n=24) received only saline. The paired pulse facilitation (PPF) in the CA1 region was also recorded. All values were presented as means±S.E.M. and ANOVA or t-tests was used for statistical analysis. The results showed that: (1) three groups of HFS successfully induced hippocampal L-LTP in control group, with average fEPSP amplitudes of 211.0±7.2%, 170.4±4.5% and 161.2±3.3% immediately, 60 min and 180 min post-HFSs, respectively; (2) in pre-HFS injection group, 0.2μg apoE4 did not change the base line synaptic transmission but significantly ($p<0.01$) inhibited the L-LTP induction, the fEPSPs being 178.3±5.8%, 149.7±5.0% and 142.2±5.0% at the same time points as control group; (3) in post-HFS injection groups, the same concentration (0.2μg) of apoE4 produced a slight, but not significant decrease in the average fEPSP amplitude ($p>0.05$); further, injection of high dose (2μg) ApoE4 after HFS did not enhance the suppression of L-LTP, the fEPSPs still being 152.2±6.6% and 150.7±4.2% at the same time points ($p>0.05$); (4) ApoE4 injection did not affect the PPF, the values before HFS being 164.8±3.4% and 163.2±3.0% in control and ApoE4 (0.2μg) groups, respectively ($p>0.05$); the values after HFS being 132.1±2.4%, 132.9±2.0% and 127.7±3.7% in control, 0.2μg ApoE4 and 2μg ApoE4 groups, respectively ($p>0.05$). These results indicate that ApoE4 injection before HFS, not after HFS, impaired hippocampal L-LTP, suggesting that neurotoxicity of ApoE4 is mainly involved in the suppression of L-LTP induction, but not the maintenance. In addition, the unaffected PPF suggests that the inhibition of L-LTP induction by ApoE4 may be not mediated by presynaptic neurotransmitter release, but postsynaptic signaling.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA097

Neuroprotective effects of Lycium barbarum L on senescence-accelerated mouse

Z. Miao and Y. Wang

Ningxia Medical University, Yinchuan, China

Lycium barbarum L. also called wolfberry, is a Chinese medicine herb which has been used for thousands of years for the purpose of healthy aging. The content of polysaccharide(LBP) in Lycium barbarum L is more than 40%. While neuroprotective effects of the LBP in neuronal cultures have been demonstrated, it is doubtful whether the LBP can cross through blood–brain barrier to elicit neuroprotection. Therefore, experiments in animal model of senescence-accelerated mouse (SAMP8) were performed to investigate its neuroprotective effects. Early Alzheimer's disease (AD) is with decreased nicotinic acetylcholinereceptor (nAChR) density from the cortex and hippocampus. α7 nAChRs expressed on cholinergic projection neurons and target regions have been implicated in neuroprotection against β-amyloid (Aβ) toxicity and maintenance of the septohippocampal phenotype. And some studies have determined that oxidative stress is also a decisive factor in AD. For experiments, adult male SAMP8 (5 months with weights 21–24 g) were housed in temperature-controlled animal room subjected to a 12-h light/12-h dark cycle and provided with sufficient food and water supply.The LBP was dissolved in phosphate-buffered saline (PBS). Animals were fed daily with 0.5 ml of either PBS or different dosages of LBP, including 50 and 100mg/kg, for a total of 8 week. We arbitrary chose 1 week for the experiment as Chinese usually drinks the soup containing Lycium barbarum L. for several days.The results suggest that LBP could prevent the appearance of aging sign and symptoms.From Morris Water Maze experiment, we found that taking different dosages of LBP could improve the learning and memory of SAMP8. Under electron and light microscope, we observed that the injuries of the brain was obviously meliorated after taking LBP and the possible mechanism might be related to upregulation of α7nAChRs level and improvement of antioxidant ability.LBP may have potential therapeutic applications to various neurodegenerative disorders.

14-3-3 regulates hippocampal long-term petentiation in mice

H. Qiao[2,1], M. Foote[2], Y. Wu[2] and Y. Zhou[2]

[1]China Academy of Chinese Medical Sciences Institute of Acupuncture and Moxibustion, Beijing, China and [2]Florida state University College of Medicine, Tallahassee, FL, USA

14-3-3 proteins are implicated in the regulation of synaptic functions based on a Drosophila mutant model and mammalian neuronal cultures. To study the role of 14-3-3 proteins in vivo, we have successfully created lines of transgenic mice which were considered a functional knockout through expressing a YFP fused peptide. Our behavioral studies show that one of the founder lines (132) that has broad hippocampal transgene expression displays impaired spatial learning and memory. Here we examined the hippocampal synaptic plasticity of this founder line using electrophysiological methods. We found that the long-term potentiation (LTP) in the CA3-CA1 connection was dramatically reduced in the 132 line compared to their wildtype littermates. To further investigate the underlying mechanism, we recorded from another founder line (142) that only has CA3 transgene expression and found that LTP was not significantly altered. Interestingly, the 142 line does not exhibit a deficit in hippocampal-dependent learning and memory tasks. These findings suggest that 14-3-3 proteins play an important role in regulating synaptic plasticity, likely through a postsynaptic mechanism.

PCA099

Aging and peri-infarct depolarizations during and after ischemia in rat

A. Institoris[1], D. Clark[2], G. Kozák[1], E. Farkas[2] and F. Bari[2]

[1]Department of Physiology, University of Szeged, Szeged, Hungary and [2]Department of Medical Physics and Medical Informatics, University of Szeged, Szeged, Hungary

Spreading depolarizations (SD) are waves of transient neuronal and glial depolarization that propagate across the cortical surface in response to certain stimuli or injury. During ischemia, SD-like peri-infarct depolarizations (PIDs) occur which can impair tissue by increasing disparity between CBF and metabolism. Despite the largest predictor of stroke in patients being advanced age, there are few studies examining PIDs in aged animals. In the current study we describe electrophysiological and hemodynamic changes in young (1-2 months), middle-aged (9 months) and old (24 months) male Wistar rats exposed to mild focal ischemia. A multi-modal imaging strategy allowed for the study of synchronous changes in: membrane potential, cerebral blood volume, local blood oxygen saturation, and cerebral blood flow (CBF). Multi-modal imaging of the rat cerebral cortex was achieved via closed cranial window mounted over the right parietal bone. Images were captured of the cortex illuminated with light-emitting diodes at wavelengths either preferentially absorbed by deoxygenated hemoglobin or isobestic for deoxygenated and oxygenated hemoglobin (rep-

resenting total hemoglobin). Laser speckle contrast images and florescence images of a voltage sensitive dye (RH-1838) were also captured. The rats were continuously kept under halothane anesthesia and euthanized at the end of the experiments. A similar decrease in CBF was observed immediately following middle cerebral artery occlusion (MCAO) in young (53.8±8.1%), middle-aged (52.2±10.9%) and old rats (51.6±6.4%). Age significantly altered the total number of PIDs during and after MCAO and both middle-aged and old rats had significantly fewer PIDs than young ($p<0.05$). Depolarizations were categorized as follows: PIDs associated with membrane potential recovery (SD-like PIDs) and those without prompt recovery (terminal PIDs). Young animals had more frequent SD-like PIDs than middle-aged or old rats ($p<0.05$). Old animals experienced significantly fewer SD-like PIDs but more terminal PIDs than either middle-aged or young ($p<0.05$). Terminal PIDs were associated with a sustained reduction in local CBF (inverse hemodynamic response) but SD-like PIDs were associated with variable responses in CBF and hyperemia was associated with SD-like PIDs more frequently in young (85%) compared to old rats (58%). Age significantly altered the number, shape and hemodynamic responses of PIDs during mild stroke. Young animals had frequent PIDs, mostly associated with membrane repolarization and increased CBF. Old rats displayed frequent terminal depolarizations coupled with a lasting decrease in local blood flow. The occurrence of such depolarization events likely compromises the cortical tissue of aged animals exposed to even a short duration of focal ischemia.

PCA100

Altered neurophysiological reactivity to hypocapnia and oxidative stress in elderly healthy carriers of the common Alzheimer's risk genetic variants

N. Ponomareva[1], T. Andreeva[2], M. Protasova[2], L. Shagam[2], D. Malina[1], A. Goltsov[2] and E. Rogaev[2,3]

[1]Brain Research, Research Center of Neurology RAMS, Moscow, Russian Federation, [2]Institute of General Genetics, RAS, Moscow, Russian Federation and [3]University of Massachusetts Medical School, Worcester, MA, USA

GWAS studies have provided evidence that in addition to apolipoprotein E (ApoE) gene, CLU and PICALM polymorphisms are associated with risk of Alzheimer's disease (AD) (Harold et al., 2009; Lambert et al., 2009; Golenkina et al., 2010). Cerebrovascular dysfunction may precede cognitive decline in AD. EEG reactivity to hyperventilation (HV), which depends on hypocapnia-induced cerebral vasoconstriction, is significantly reduced in elderly carriers of AD risk variant ApoE ε4 because of the alterations of neuronal and cerebral reactivity to hypocapnia (Ponomareva et al., 2012).
This study was aimed at determining whether the changes of EEG reactivity to HV in normal aging depend on CLU and PICALM polymorphisms.
We examined EEG in resting and under HV in 102 healthy volunteers (age range 28-75 years), stratified by CLU (rs11136000) and PICALM (rs3851179) genotypes. The effectiveness of HV was verified by measuring the end-tidal CO2. The effect of ApoE genotype on EEG was controlled. Informed written consent was obtained from all participants. The experimental protocol of this study was approved by the local Ethics Committee. The presence of AD risk variant CLU CC was associated with the reduction of EEG reactivity to HV during aging. In the CLU CC carriers EEG reactivity to HV decreased with age, while in the CLU CT&TT carriers the changes in EEG reactivity were smaller. The relative theta power under HV showed a negative correlation with age in CLU CC but not in CLU CT&TT subjects. The older CLU CC carriers under HV had lower delta and higher alpha relative powers as compared to the older CLU CT&TT carriers. Similar alterations were associated with PICALM polymorphism. In the elderly carriers of AD risk variant PICALM GG, HV-induced changes of EEG were reduced as compared to the noncarriers. The effect of PICALM on EEG was not attributable to the interaction with CLU or APOE genotypes.
Our observations suggest altered neuronal and cerebrovascular reactivity to hypocapnia in the elderly carriers of CLU and PICALM AD risk variants. In the CLU CC, as well as in the ApoE ε4 carriers, the EEG alterations may be due to the endothelial dysfunction as a consequence of cerebral amyloid angiopathy and atherosclerosis (Miwa et al., 2005). PICALM is involved in clathrin-mediated endocytosis and regulation of Aβ generation (Xiao et al., 2012). PICALM is predominately present in endothelial cells and may participate in Aβ transport across blood-brain barrier (Baig et al., 2011). These processes may be related to the abnormal cerebrovascular regulation in the older carriers of PICALM risk variant for AD. Impaired cerebrovascular reactivity may irreversibly damage the vulnerable areas of the brains through long-term hypoxemia. The results suggest the involvement of vascular factors in AD pathogenesis.

PCA101

Melatonin treatment could regulate the levels of pro/anti-inflammatory cytokines in brain of senescence accelerated mouse

G. Yoldi[1], R. Kireev[1], E. Vara[2] and J. Tresguerres[1]

[1]Physiology, Complutense University of Madrid, Madrid, Spain and [2]Biochemistry and Molecular Biology, University Complutense of Madrid, Madrid, Spain

Neuro-inflammation has been proposed as a causative factor of neurological diseases and disorders during the ageing process. The senescence-accelerated mouse (SAM) is known to be a good murine model for accelerated aging.
The aim of this research was to investigate the effect of aging on inflammation in brains obtained from SAMP8 and SAMR1 male mice and the influence of chronic exogenous administration of melatonin.
Animals of 2 (young) and 10-11 months of age (old) were used. The influence of the administration of melatonin in the drinking water for one month at two different dosages (1 and 10 mg/kg/day) on brains of old mice was studied. The levels of pro/anti- inflammatory cytokines were studied by ELISA.
During ageing the level of IL 2 was increased in brain of both mice strains as compared to young animals. However, the level of this cytokine was higher in old SAMP8 as compared with SAMR1 of the same age. The levels of TNF-α and IL 6 were

also increased significantly in brains of SAMP8 and SAMR1 old male mice as compared to young animals. Melatonin treatments in both doses were able to decrease levels of IL2, TNF-α and IL 6 in both strains of mice.
The levels of anti-inflammatory cytokines (IL 4 and IL 10) were decreased in the brain of old SAMP8 male as compared with young mice. Interestingly, the levels of these cytokines did not show differences between young and old SAMR1 male animals. Differences between strains were observed with higher levels of anti-inflammatory cytokines in old SAMR1 as compared with SAMP8 animals of the same age. After chronic treatment with melatonin a significant increase in levels of IL 4 and IL 10 were detected in group of old SAMP8, but not in the case of SAMR1 male mice.
We have demonstrated that in brain of old SAMP8 mice the levels of pro-inflammatory cytokines were increased, but the anti-inflammatory were decreased as compared with SAMR1. Increases in pro-inflammatory cytokines in the brain may be involved in the age-related neural dysfunction and/or learning deficiency in SAMP8 mice. Melatonin treatment was able to improve the dysbalace of neuro-inflammation in brain.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA102

Estrogen and melatonin treatments improved neuroinflammation processes in dentate gyrus of ovariectomized female rats

R. Kireev[1], G. Yoldi[1], E. Vara[2] and J. Tresguerres[1]

[1]Physiology, Complutense University of Madrid, Madrid, Spain and [2]Biochemistry and Molecular Biology, University Complutense of Madrid, Madrid, Spain

The aim of the present study was to investigate the effect of aging and ovariectomy on neuro- inflammation in dentate gyrus of the hippocampus obtained from old female rats and the influence of chronic exogenous administration of estrogens (Eos) and melatonin (Mel) on these.
Thirty-six female Wistar rats of 22 months of age were used. Twelve of them remained intact, and the other 24 were ovariectomized at 12 months of age. Ovariectomized animals were divided into 3 groups and treated for 10 weeks with Eos, Mel or saline. All rats were killed by decapitation at 24 months of age and dentate gyri were collected. A group of 2 month old intact female rats was used as young control. The levels of TNFα, IL1β and IL6 were analysed by ELISA. The expression of TNFα, IL1β, GFAP, nNOS, iNOS, HO-1 and NFkB genes were detected by RT-PCR.
The levels of IL1β and IL6 were significantly elevated in the dentate gyrus of old rats as compared to young ones, and this effect was more evident in ovariectomized animals. The mRNA expression of IL1β was also increase in old intact and ovariectomized females as compared to young. No statistically significant differences were observed between TNFα levels of intact and castrated old female rats. However, a significant increase in mRNA expression of TNFα of ovariectomized versus the old intact group was observed. Administration of Eos and Mel to the ovariectomized females significantly decreased both levels and gene expression of pro-inflammatory cytokines.
Aging significantly increased mRNA expression of iNOS, HO-1 and NFkB and these changes were more marked in ovariectomized animals. The expressions of these genes were significantly attenuated after Eos and Mel replacement in the group of castrated females.
The dentate gyrus of aged rats showed a highly significant increase in mRNA expression of GFAP and ovariectomized rats showed an additional increase. Administration of Eos to the ovariectomized females significantly decreased this parameter, but this was not the case in those treated with Mel.
The results revealed that chronic administrations of Eos and Mel were able to prevent the ovariectomy-induced increase in the levels of pro-inflammatory cytokines and also in the up-regulation of GFAP and NFkB in the dentate gyrus as observed in intact rats.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA103

Haematological, biochemical and physical changes during blood storage in three different blood bags

R.O. Nneli[1,3], J.O. Chukwu[2,3] and M.O. Okhiai[1,3]

[1]Physiology, Federal University of Ndufu Alike Ikwo, Ndufu Alike Ikwo, Ebonyi, Nigeria, [2]Physiology, Ebonyi State University, Abakaliki, Ebonyi, Nigeria and [3]Physiology, Abia State University, Uturu, Abia, Nigeria

Whole blood stored in blood bags with anticoagulants in the blood banks and the condition of the blood determines its viability for transfusion (Duta, 2006). The loss of essential components of blood during storage is still a major problem in our environment. Commonly used anticoagulants are known to have effects on the quality of blood (Bailey and Dove, 1975; Kyou, 1990). We investigated the haematological, biochemical and physical changes during blood storage using the three different blood bags namely: ACD, CPD and CPDA1 bags. Venous blood obtained from 15 apparently healthy male volunteers (18 – 50 years old) divided into 3 groups of 5 males were placed into ACD, CPD and CPDA1 blood bags respectively. The haematological, biochemical and physical profile of the stored blood were determined using standard procedures at weekly intervals for 35 days. The results showed that the red cell indices (Hb concentration, red cell mass, haematocrit, MCV, MCH, MCHC) as well as biochemical parameters declined gradually in ACD while blood showed physical deterioration. In the CPD bags, the profiles showed better integrity while in the CPDA1 bags, no change occurred as the integrity of the parameters were well maintained through out the period of study ($p<0.05$). It is concluded that blood stored in CPDA1 bags had a greater viability, initial survival, long life of red blood cells, preservation and net loss of intracellular potassium ions was less. The specific gravity and the integrity of 2, 3 DPG were maintained. No physical deterioration was observed in the Blood stored in CPDA1 bags as compared with the ACD and CPD bags. CPDA1 anticoagulant bags should be recommended as the bag of choice.

PCA104

Potential ameliorative role of honey supplementation against the adverse effects of exposure to gasoline on red cell indices and bone marrow megakaryocytes in Sprague-Dawley male rats

M.B. Abubakar[1,2], W.Z. Abdullah[3], S.A. Sulaiman[4] and A.B. Suen[2]

[1]Physiology, Usmanu Dan Fodiyo University, Sokoto, Nigeria, [2]Physiology, Universiti Sains Malaysia, Kota Bharu, Kelantan, Malaysia, [3]Haematology, Universiti Sains Malaysia, Kota Bharu, Kelantan, Malaysia and [4]Pharmacology, Universiti Sains Malaysia, Kota Bharu, Kelantan, Malaysia

Gasoline (petrol) is primarily used as fuel for internal combustion engines. Different health risks including haematotoxicity and oxidative stress have been reported for gasoline [1, 2]. Although Malaysia has in the recent years adopted the European fuel quality standards in order to help improve the air quality in the environment, gasoline with Research Octane number 95 (believed to contain benzene and other toxic substances) is still widely in use [3]. Supplementation with antioxidants such as vitamins A, C, and E has been shown to ameliorate the toxicity effects of gasoline vapours exposure [4]. Honey contains vitamins, and polyphenols that possess good antioxidant properties [5].The potential role of honey in preventing gasoline-induced adverse effect on red cell indices and bone marrow megakaryocytes was investigated. Thirty two male rats weighing 170-230g were randomly assigned in to 4 groups (n=8) namely, control (C; given 0.5ml distilled water + exposure to ambient air daily); gasoline exposed (G; exposed to gasoline vapours 11.13±1.1cm3/h, 6h daily, 6 days/week + 0.5ml water daily); honey treated (H; given honey 1.2g/kg body weight daily) and gasoline exposed + honey treated (GH; exposed to gasoline vapours as above and concurrently treated with honey 1.2g/kg body weight daily) At the end of 11 weeks, rats were sedated with itraperitoneal pentobarbitone (100mg/kg body weight) and blood samples for full blood count (FBC) and differential count (DC) were collected by cardiac puncture. Rats were sacrificed (over dosage of pentobarbital) and bone marrow was collected for smear which was stained and examined under the light microscope. Both normal and abnormal megakaryocytes (with disintegrated and/or detached nuclei) were counted and the percentage of abnormal ones was determined for each rat. Data were analyzed using Kruskal-Walis test followed by Mann-Whitney U test. Results are expressed as median (interquartile range). The mean corpuscular haemoglobin concentration (MCHC) was found to be significantly ($p<0.05$) reduced in G [31.0 (2.0)] compared with C [(33.5 (3.0)] and H [33.0 (4.0)], it was however not significantly different compared with GH [32.0 (0)]. The percentage of abnormal megakaryocytes was significantly ($p<0.05$) higher in G [18.1 (15.9)] compared with C [2.7 (4.4)], H [4.5 (4.0)] and GH [4 (3.7)]. This suggests that gasoline vapours inhalation was associated with adverse alterations in MCHC and bone marrow megakaryocytes of rats and administration of honey has the potential to improve such changes in rat model.

Detailing peripheral nerve activities by oligofiber recordings: a resolution of sympathetic nerve discharge

C. Su[1], C. Chiang[1,2], Y. Fan[1] and C. Ho[2]

[1]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan and [2]Department of Anesthesiology, Taipei Veterans General Hospital and National Yang-Ming University, Taipei, Taiwan

Whole-bundle nerve recording is an easy technique to gauge peripheral nerve activities. However, this conventional technique fails to detail individual fiber activities. Aiming for a signal resolution at the single-fiber level, we established a relatively novel experimental model so-called 'oligofiber recordings'. In vitro splanchnic sympathetic nerve–thoracic spinal cord preparations were obtained from Sprague-Dawley neonatal rats. Whole-bundle splanchnic nerves were incubated in a glass micropipette containing 0.5% collagenase for 90 min. The dissociated nerve fascicles were then brought into a small caliber micropipette for electrical signal recordings. Oligofiber activities that displayed several distinct spike potential waveforms were often achieved. Automation of spike sorting was based on spike waveform features using a series of custom-made LabVIEW programs incorporated with MATLAB scripts. Spike data were automatically grouped by k-means clustering algorithms followed by verification of their waveform homogeneity by principal component analysis (PCA). Dissimilar waveforms with exceeding Hotelling's T2 distances from the cluster centroids were retrieved by a subtraction algorithm (SA), which partially resolved overlapped spikes. Both T2-selected and SA-retrieved spikes were combined as unit activities. To evaluate if unit activities truly originated from single fibers, we examined the probability distribution of interspike intervals (ISIs) and determined if a change of waveform features was a function of their preceding ISIs. Using the oligofiber recording techniques, we could simultaneously examine, on average, ~3 single fiber activities per experiment. With some modifications, these techniques should be applicable to any peripheral nerve recordings.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA106

Deregulation of adrenomedullin system in cerebellar vermis of hypertensive rats

A. Stern Israel and L. Figueira

Lab of Neuropeptides, School of Pharmacy, Universidad Central de Venezuela, Caracas, Distrito Capital, Venezuela, Bolivarian Republic of

Adrenomedullin (AM) is a 52-amino acid peptide with important functions in cardiovascular regulation. AM has two specific receptors formed by the calcitonin-receptor-like receptor (CRLR) and receptor activity-modifying proteins (RAMP2, RAMP3), known as AM1 and AM2 receptors, respectively. In addition, AM has affinity for the calcitonin-gene-1 related peptide receptor (CGRP1), composed of CRLR+RAMP1. In brain, AM and their receptors are found in localized areas, including cerebellum. We found by quantitative autoradiography an increase in cerebellar AM density binding sites during hypertension, suggesting a role for cerebellar AM-system in blood pressure regulation. Thus, we assessed whether there is an altered expression of AM and its receptor components in the cerebellar vermis of male adult spontaneously hypertensive rats (SHR) and normotensive control Wistar Kyoto rats (WKY), of 8 and 16 weeks old. Animals were euthanized by decapitation; the cerebellar vermis was dissected, placed in lysis buffer, homogenized and centrifuged. The expression of AM, RAMP1, RAMP2, RAMP3 and CRLR was performed by Western blotting. The experiments were conducted according to good practice for the management of laboratory animals of the Bolivarian Republic of Venezuela and the approval of Animal Ethical Committee of the School of Pharmacy. Values are expressed normalized to β-actin expression as means ± S.E.M., compared by ANOVA. Our findings demonstrate a higher expression of CRLR (8 weeks vs. 16 weeks: WKY= 1.0±0.09 vs. 4.1±0.2 and SHR= 1.0±0.08 vs. 5.1±0.2), RAMP1 (8 weeks vs. 16 weeks: WKY= 1.0±0.03 vs. 4.1±0.1 and SHR= 1.0±0.09 vs. 5.1±0.2) and RAMP3 (8 weeks vs. 16 weeks: WKY= 1.0±0.03 vs. 4.1±0.2 and SHR= 1.0±0.09 vs. 5.1±0.1) in cerebellum of 16 weeks old compared to 8 weeks old rats, both in WKY and SHR rats. While, AM and RAMP2 expression was not altered with rat age. In addition, we found a higher CRLR, RAMP1 and RAMP3 expression and a reduced expression of AM and RAMP2 in the cerebellar vermis of SHR rats when compared with WKY rats, both in 8 and 16 week old rats (AM, 8 weeks old= WKY vs. SHR: 1.0±0.08 vs. 0.6±0.02; 16 weeks old: 1.0±0.09 vs. 0.55±0.03) (RAMP2, 8 weeks old= WKY vs. SHR: 1.0±0.09 vs. 0.55±0.02; 16 weeks old: 1.0±0.09 vs. 0.7± 0.02) (RAMP1, 8 weeks old= WKY vs. SHR: 1.0±0.07 vs. 1.45±0.08; 16 weeks old: 1.0±0.08 vs. 1.55±0.07) (RAMP3, 8 weeks old= WKY vs. SHR: 1.0±0.01 vs. 2.45±0.12; 16 weeks old: 1.0±0.08 vs. 1.55±0.05) (CRLR, 8 weeks old= WKY vs. SHR: 1.0±0.07 vs. 1.53±0.09; 16 weeks old: 1.0±0.07 vs. 1.45±0.08). Our findings demonstrate an age dependent expression of cerebellar AM system which is deregulated during hypertension, suggesting a novel functional role of cerebellar AM in the regulation of blood pressure.

Orexin-neuromodulated cerebellar folium-p-parabrachial microcomplex adaptively controls redistribution of arterial blood flow for defense behavior

N. Nisimaru[1,2], A. Arata[3,1], T. Hashikawa[1], S. Nagao[1] and M. Ito[1]

[1]RIKEN Brain Science Institute, Wako, Saitama, Japan, [2]Physiology, Oita University, Faculty of Medicine, Yufu, Oita Prefecture, Japan and [3]Physiology, Hyogo College of Medicine, Nishinomiya, Hyogo, Japan

We so far reported that Purkinje cells in a small area (folium-p, fp) of rabbit cerebellar flocculus receive excitatory modulation via diffuse axons of hypothalamic orexinergic neurons (1). Rabbits were preferred because their flocculus has discernible regular folial divisions; this is not the case in rats or mice. We used albino rabbits weighing 1.0-3.1 kg. In the study to be reported, we used axonal transport of DiI and biotinylated dextran amine and found that these Purkinje cells project to the ventrolateral edge of the ipsilateral parabrachial nucleus (PBN), thus forming the fp-PBN microcomplex. Because stimulation of the classic defense area that activates hypothalamic orexinergic neurons induced, as part of defense reactions, redistribution of arterial blood flow between active muscles and visceral organs/resting muscles, we hypothesized that fp-PBN microcomplex adaptively controls the redistribution of arteriasl blood flow, which is primarily controlled by somatosympathetic reflexes (SSRs) and their supraspinal pathways. To support this hypothesis, we previously showed that climbing fiber signals to fp Purkinje cells were elicited by high arterial blood pressure or a high potassium concentration in muscles, both implying errors in redistribution of arterial blood flow (2). In the present study, we evoked defense reactions by applying electric foot shock stimuli to a conscious freely moving rabbit in a cage. The stimuli were 2-4mA, lasting 1-30 s in each trial and repeated once every 10 min 4-7 times in one session. These stimuli evoked quick turning around of the rabbit within the cage. Probes were chronically implanted to measure blood flow in femoral and celiac arteries under α–chloralose (60 mg/kg) and urethane (600 mg/kg) anesthesia. Another probe was implanted to measure blood pressure in femoral artery. Foot shock stimuli induced an increase in arterial blood flow in femoral muscles (FAF) and a reciprocal decrease in visceral organs (VAF). Both the increase and decrease were attenuated after systemic administration of orexin antagonists. After fp lesioning (with local kainate injection), FS-induced FAF increases became significantly larger, whereas FS-induced VAF decreases became significantly smaller and shorter- lasting. Apparently, under orexin neuromodulation, fp functions for effective balance of arterial blood

flow in magnitude and time course between active muscles and visceral organs/resting muscles. Based on these collected data, we conclude that folium-p and PBN jointly form a unique microcomplex that is activated by orexin neuromodulation in defense behavior, and that the so activated microcomplex adaptively controls redistribution of arterial blood flow conforming to the high demand of arterial blood supply to active muscles in defense behavior.

PCA109

Contribution of spinal μ-opioid receptors to inhibition of heat-induced heart rate response by touch in anesthetized rats

N. Watanabe, P. Mathieu and H. Hotta

Department of Autonomic Neuroscience, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan

It is common experience that pain subsides by touching the skin near the painful site although the mechanism has not been fully elucidated yet. We previously reported that touch (gentle mechanical cutaneous stimulation) inhibited the somatocardiac sympathetic C-reflex evoked by excitation of unmyelinated C-afferent fibers in anesthetized rats (1-2). Such an inhibitory effect was greater when touch was applied to ipsilateral and closer spinal segment to C-afferent input, and was significantly reduced by i.v. injection of non-specific opioid receptor antagonist, naloxone (1). Thus, the present study examined whether the effect of touch is mediated via spinal opioid receptors. Also, we attempted to clarify the subtype of opioid receptors contributing to this effect. For these purposes, we employed tonic noxious heat stimulation in deeply-anesthetized rats.

Experiments were performed on male Wistar rats (5-6 months), that were under urethane anesthesia (1.4 g/kg s.c.). The trachea was cannulated for artificial ventilation. A common carotid artery and jugular vein were catheterized for recording blood pressure and heart rate (HR) and supplying anesthetics and other substances, respectively. A catheter was implanted in the spinal subarachnoid space at the lumbar enlargement level (3) for intrathecal injection of saline or opioid receptor antagonists (5 rats in each group). Heat stimulation (at 46-48°C for 45-43 seconds, respectively) was applied to the lower back using a Peltier thermode at fixed intervals. The same temperature and duration of heat stimulation was used throughout the experiment. Touch was applied to the right inner thigh for 10 minutes using a soft elastomer brush (1-2). Statistical analyses were performed using the one-way factorial or repeated measures ANOVA followed by Bonferroni's multiple comparisons test and statistical significant level was set at $p < 0.05$. Data were expressed as mean ± SEM.

Heat stimulation altered HR by 11.2 ± 0.62 beat per minutes. Evoked HR responses were significantly inhibited by touch in the saline group. The inhibition occurred during touch (by 27.9 ± 7.1 % of pre-touch response) and continued at 10-15 minutes after touch (by 31.8 ± 7.2 %). In the naloxone and CTOP (μ-opioid receptor antagonist) groups, the inhibitory effect of touch was not observed. In the naltrindole (δ-opioid receptor antagonist) group, heat-induced HR responses were inhibited during touch (by 36.7 ± 6.8 %). Prior to touch, the magnitude of heat-induced HR responses and basal HR did not differ between groups. Basal HR over the experimental period was stable in all groups.

The present study results suggest that touch inhibits nociceptive transmission into autonomic reflex pathways predominantly via μ-opioid receptors in the spinal cord.

PCA110

Provocative motion elicits hypothermia and tail vasodilation in rats and shrews: A new index of nausea in pre-clinical studies?

S. Ngampramuan[1], M. Cerri[2], F.D. Vecchio[2], A. Kamphee[1], J. Rudd[3] and E. Nalivaiko[4]

[1]Research Center for Neuroscience Molecular Biosciences, Mahidol University, Nakhon Pathom, Thailand, [2]Biomedical and Motor Sciences, University of Bologna, Bologna, Italy, [3]School of Biomedical Sciences, Chinese University of Hong Kong, Hong Kong, Hong Kong and [4]School of Biomedical Sciences and Pharmacy, University of Newcastle, Newcastle, NSW, Australia

Nausea elicited by chemo- and radiotherapy, surgical intervention with anaesthesia, motion, and during pregnancy, is a major clinical problem as it is often resistant to anti-emetic drugs1. In contrast to the well-defined pathways mediating vomiting, the neural circuitry responsible for nausea is poorly understood, largely due to the lack of adequate indices of nausea in preclinical studies. Most mechanistic studies on nausea in humans come from perturbing vestibular or visual stimulation. The resulting cardinal symptoms of motion sickness are cold sweating, nausea and vomiting, and facial pallor; a few studies also report motion sickness-related hypothermia2 from cutaneous vasodilation in the limbs3. The aim of the present studies, therefore, was to investigate if similar motion-induced responses are present in rats and in house musk shrews (Suncus murinus – an insectivore possessing vomiting reflex).

Under isoflurane anesthesia (2% in O2), adult male Wistar rats were implanted with telemetric transmitters to record core body temperature. One week later, the animals were administered 5-HT3 receptor antagonist ondansetron (0.5 mg/kg s.c.) or vehicle, and 30 min later were subjected to provocative motion (rotation 0.5 Hz, 40 min) in their home cages; the experiment was repeated one week later using a crossover design (n=7). The rotational stimulus provoked mild hypothermia (from 37.4±0.1 to 35.6±0.2°C, $p<0.001$) that was attenuated by ondansetron by 28% ($P<0.05$). In another groups of rats (un-instrumented, n=6) we used infrared thermography and found that rotation induced a transient increase of tail temperature (from 22.9±0.6 to 25.1±0.6°C $p<0.05$) indicative of vasodilation; this rise appeared to precede the fall in the core body temperature seen in the telemetered studies. Infrared thermography was also used to investigate skin temperature changes induced by motion (linear shaker, 1 Hz, 15

min) in S. murinus (n=6). All animals exhibited episodes of retching and/or vomiting (latency = 205±38 s) that was preceded by a transient increase in tail temperature (from 24.0±1.5 to 27.0±2.2°C, p<0.05). A fall of interscapular temperature (from 38.4±0.5 to 36.6±0.4°C, p<0.001) was also seen during motion testing.

In conclusion, provocative motion appears to induce hypothermia via mechanisms presumably involving dilatation of the vascular bed of the tail. The tail vasodilation that precedes retching/vomiting in S. murinus, and the tail vasodilation in rats could form the basis of a potential index of nausea in experimental animals. The poor effect of ondansetron was predicted since it does not prevent motion sickness-induced nausea in man.

PCA111

The drive to breathe is tuned via multi-path modulation of inhibitory tonic expiratory neurons in the ventral respiratory column (VRC) network

B. Lindsey[1], L.S. Segers[1], S.C. Nuding[1], M.M. Ott[1], J.B. Dean[1], D.C. Bolser[2], R. O'Connor[1] and K.F. Morris[1]

[1]Molecular Pharmacology and Physiology, USF Morsani College of Medicine, Tampa, FL, USA and [2]Physiological Sciences, University of Florida, Gainesville, FL, USA

Models of the medullary VRC include rostral inspiratory (I) neurons that excite more caudal I neurons, including premotor populations, as well as inhibitory I neurons that act via recurrent and feed-forward connections upon other excitatory and inhibitory I and expiratory (E) neuron populations (1). Our prior work supported the hypotheses that tonic E (t-E) neuron inhibition of premotor I neurons contributes to baroreceptor-evoked reductions in I drive (2), and that central chemoreceptor stimulation enhances drive, in part via reduced I-phase t-E neuron activity and the resulting disinhibition of premotor neurons (3). Aims of the present work were to identify further the functional connections of t-E neurons and test the hypothesis that carotid peripheral chemoreceptors also modulate drive by I-phase inhibition of t-E neurons. Spike trains were acquired by multi-electrode arrays along with signals from phrenic and vagus nerves (10 Hz–10 kHz) from 22 adult cats. Animals were anesthetized with isoflurane mixed with air (induction: 5% ; maintenance: 0.5–3.0%) until decerebration, neuromuscularly blocked (pancuronium bromide; initial bolus 0.1 mg kg–1 followed by 0.2 mg kg–1 hr–1, iv;) and monitored (4), vagotomized, and artificially ventilated. Arterial blood pressure, end-tidal CO2, tracheal pressure, and arterial PO2, PCO2, and pH were monitored. In 6 recordings from 5 animals, yielding data from 219 neurons (4,374 distinct cell pairs), carotid chemoreceptors were stimulated (5 trials) by close 30-s injections of 1.0 mL of a CO2 –saturated 0.9% saline solution. Responses were identified using a bootstrap-based statistical method; p-value threshold was set with a false discovery rate of 0.05 (4). Cross-correlogram features were identified using cycle-shifted surrogates (3) or a Monte-Carlo test with surrogate spike trains (5) generated with a gamma distribution shape parameter; false discovery rate < 0.05. Features in spike-triggered averages of full-wave rectified phrenic signals were identified (3) using a two-sided Wilcoxon signed-rank test (Bonferroni correction; p < 0.05). Overall, from 171 peri-columnar t-E neurons we identified 42 of 599 pairs with cross-correlogram central peaks (detectability index (di) = 13.0 ± 11.8 SD; half-width (hw) = 18.5 ms ± 25.7). Results from the stimulation experiments included assemblies with 8 correlogram troughs indicative of t-E neuron inhibition of I neurons (di = 7.9 ± 2.9; hw = 10.8 ms ± 9.6) and disinhibitory enhancement of I drive. When considered with results from simulations of a computational neuromechanical model for cough (1) and associated in vivo data, we conclude that multiple afferent systems and behaviors exert a "push-pull" control of I drive through modulation of a coordinated network of t-E neurons.

PCA112

The Basic Rest-Activity Cycle (BRAC) is present in transgenic rats with ataxin3-mediated destruction of orexin neurons, but amplitudes of the BRAC-associated brown adipose tissue and body temperature change are reduced

B. Blessing[1], M. Mohammed[1], Y. Ootsuka[1] and M. Yanagisawa[2]

[1]Human Physiology, Flinders University, Adelaide, SA, Australia and [2]Department of Molecular Genetics, University of Texas Southwestern Medical Centre, Dallas, TX, USA

In undisturbed Sprague-Dawley rats, with ad libitum access to food and water, body and brain temperatures increase, in association with blood pressure, heart rate, behavioural activity and food intake, approximately every 1-2 hours, and brown adipose tissue (BAT) thermogenesis contributes to the temperature increases (Blessing et al., 2012). Hypothalamic orexin-containing neurons (de Lecea et al., 1998; Sakurai et al., 1998) influence appetite, the sleep-wake cycle, locomotor activity and other physiological variables (Kuwaki, 2011). We have now assessed BRAC-related parameters in conscious unrestrained transgenic (TG) Sprague Dawley rats with ataxin3-mediated destruction of orexin neurons (Beuckmann et al., 2004) in comparison with their wildtype littermates (WT). Under inhaled

isoflurane (2% in oxygen) anaesthesia, TG (n=11) and WT (n=9) male rats (300-450 g) were instrumented with chronically implanted thermistors to measure BAT and body temperature (Blessing et al., 2012). All surgical procedures were performed in accord with the Animal Welfare Ethics Committee of Flinders University. Thermistor cables were passed subcutaneously and connected to a headpiece fixed to the skull with dental cement. After one-week recovery the unrestrained TG or WT rats were housed singly in a quiet closed temperature controlled (24-26°C) cage, with ad libitum access to food and water, and with 12 hour dark/light cycling. Behavioural activity was measured with an infrared grid system. Group results (mean ± SEM) were analysed with factorial ANOVA. There was no difference in the timing of the dark active period BRAC-related episodic BAT temperature peaks between TG and WG rats (106±3 min in TG and 111±3 min in WT, $p>0.05$). However the amplitude of the behavioural activity (7±1 units in TG versus 11±1 units in WT rats, $p<0.05$) and the increases in BRAC-related BAT temperature (1.22±0.02°C in TG and 1.42±0.03°C in WT, $p<0.001$) and body temperature (0.80±0.01°C in TG versus 0.90±0.02 in WT, $p<0.001$) were reduced in the transgenic animals. The difference between BAT and body temperatures was also reduced in the transgenic animals versus the wild type animals (+0.44±0.02°C in TG and +0.55±0.03 °C in WT, $p<0.001$) suggesting that reduced BAT thermogenesis contributes to the reduced BRAC-related increase in body temperature in transgenic animals. Thus the BRAC organization of daily life does not depend on the function of the orexin-containing neurons, but activity of these neurons contributes to the amplitude of BRAC episodes. Our results suggest that orexin-containing neurons increase the intensity with which rats periodically engage with the external environment.

PCA113

Sudden access to live cochroaches increases brown adipose tissue (BAT) thermogenesis in conscious unrestrained rats

B. Blessing, M. Mohammed and Y. Ootsuka

Human Physiology, Flinders University, Adelaide, SA, Australia

Body and brain temperatures increase when Sprague-Dawley rats explore the external environment, and brown adipose tissue (BAT) thermogenesis contributes to the temperature increases (Ootsuka et al., 2009, Blessing et al., 2012). We have now assessed whether a salient novel environmental event activates BAT thermogenesis. Under inhaled isoflurane (2% in oxygen) anaesthesia, 5 male Sprague-Dawley rats (300-450 g) were instrumented with chronically implanted thermistors to measure BAT and body temperature (Blessing et al., 2012). All surgical procedures were performed in accord with the Animal Welfare Ethics Committee of Flinders University. Thermistor cables were passed subcutaneously and connected to a headpiece fixed to the skull with dental cement. After one-week recovery the unrestrained rats (n=9) were housed singly in a quiet closed temperature controlled (24-26°C) cage. A stocking-mesh bag containing 4 live cockroaches (Periplaneta australasiae) was suddenly introduced into the rat's cage. We recorded BAT and body temperatures for 30 min and then removed the cockroach bag. The rat approached the bag of cockroaches and attempted to bite or rip the stocking-mesh bag. Maximum increases in BAT and body temperatures (mean ± SEM) were recorded and analysed with repeated measures ANOVA. The increase in BAT temperature (1.1±0.16°C) was significantly greater ($P<0.05$) than the simultaneously measured increase in body temperature (0.76±0.11°C), suggesting that BAT thermogenesis contributes to the increase in body temperature. Our results suggest that brain regulated sympathetically-controlled BAT thermogenesis contributes to the increase in body temperature occurring when the rat is confronted with a novel salient stimulus.

PCA114

Withdrawal of oestrogen elicits changes in the expression of GABA receptors and markers of GABA transmission in the nucleus of the solitary tract

E. Spary, M.J. Drinkhill, S. Crossland, A. Maqbool and T.F. Batten

Cardiovascular and Diabetes Research, University of Leeds, Leeds, UK

Oestrogen is a known to act centrally as a modulator of autonomic function. Our previous study showed changes in oestrogen receptor (ER) subtype expression in the nucleus of the solitary tract (NTS), an area of the brainstem regulating autonomic

reflexes, are associated with fluctuating plasma oestrogen levels during the oestrous cycle and after ovariectomy (OVX)[1]. GABA transmission in the NTS is critical for baroreflex control of blood pressure (BP) and as the promoter sequences for several receptors, receptor associated proteins, enzymes and transporters involved in GABA transmission include potential oestrogen response element consensus sites we analysed mRNA expression levels for these markers in the NTS of normal cycling and OVX female rats. Female Wistar rats (approx. 150g, n=6) fed a phytoestrogen free diet were subjected to OVX or sham-OVX under anaesthesia (isofluorane, 5% in O_2). Radiotelemetry probes (DSI) were implanted to record from the left carotid artery. BP, heart rate and activity levels were recorded for 3 or 6 weeks post surgery, at which point rats were killed under the same anaesthetic conditions. Micropunches of NTS tissue were taken for reverse transcription of mRNA and analysis by real-time PCR. Percentage body weight gain after 6 weeks in OVX rats (45.48 ± 1.1%; mean ± SE) was significantly greater than in sham-OVX rats (28.68 ± 1.7%, p=0.01), although food intake between the two groups was consistent (approx 110-115g/animal/week). After 3 weeks increases in systolic (+3.4%) and mean (+5.3%) BP were evident in OVX rats compared to starting values. These increases continued to 6 weeks, becoming significantly different (+10.3%, p=0.05; +12.55%, p=0.05). No significant changes in BP were observed in control rats over 3 or 6 weeks. Real-time PCR for the GABA-A subunit mRNAs revealed significantly decreased expression for 4 of the 14 tested (alpha1; alpha 5; gamma3, delta) in OVX rats at both 3 and 6 weeks. Additionally, at 3 weeks a reduction in beta1 was seen, with a reduction in beta3 at 6 weeks. In contrast, mRNA for the epsilon subunit appeared up-regulated. Expression levels for the GABA-B receptor subtypes BR1 and BR2 showed significant reductions ($p<0.05$) in OVX after 6 weeks, as was the case for the GABA transporter GAT1 and the GABA receptor-associated protein GABARAP. In contrast the GABA synthesising enzyme GAD67 and the GABA receptor-associated protein like 1 GABARAPL1 were increased ($p<0.05$) in OVX after 3 weeks. The data are consistent with the hypothesis that circulating oestrogen acts on ERs in the NTS to modulate inhibitory GABAergic influences on autonomic reflexes controlling BP through affecting both GABA synthesis/release mechanisms and GABA receptor composition.

The pre-sympathetic neurons in the rostral ventrolateral medulla (RVLM) are the source of the sympathetic activity and there is evidence that these cells present intrinsic pacemaker activity. However, there are few electrophysiological studies in the literature involving these neurons in neonatal rats and no studies on these neurons in the brainstem slices from adult rats. Herein we studied slices from adult rats (5-6 weeks old) presenting viable RVLM pre-sympathetic neurons for patch-clamp recordings, previously labeled by injection of fluorescent microbeads into the intermediolateral column of spinal cord (T3-T6). Our data show that after application of antagonists of ionotropic glutamate, GABA and glycine receptors in the bath perfusion, these neurons present spontaneous firing action potentials in a regular pattern [frequency: 9.4±1.0 Hz; CV of the inter-spike interval: 0.12±0.01 (n=19)]. In comparison, RVLM respiratory neurons projecting to phrenic nucleus in spinal cord (C3-C5) fired spontaneous action potentials more irregularly and with a lower frequency when compared to pre-sympathetic neurons [frequency: 4.4±0.8 Hz; CV of inter-spike interval: 0.38 ± 0.11 (n=15); P=0.001]. Considering that CIH in rats induces hypertension due to sympathetic overexcitation, we hypothetized that the pre-sympathetic neurons in these animals should present changes in their intrinsic membrane properties and an increase in their frequency discharge. However, our data clearly indicate that the intrinsic membrane properties and the frequency discharge of the pre-sympathetic neurons in rats submitted to 10 days of CIH were not changed: resting membrane potential [Con: -63.9±0.8 mV, (n=21) vs. CIH: -64.8±0.7 mV, (n=23); P=0.41]; input resistance [Con: 341±21 MOhm, (n=18) vs. CIH: 392±34 MOhm, (n=20); P=0,21] and intrinsic frequency discharge [Con: 9.4±1,0 Hz, (n=19) vs. CIH: 9.9±1.2 Hz, (n=21); P=0.74]. The present study shows that: a) it is feasible to record the electrophysiological properties of RVLM pre-sympathetic neurons in brainstem slices from adult rats, b) these neurons present characteristics of pacemakers, and c) their passive and active intrinsic properties were not altered in rats submitted to CIH.

Voluntary wheel-running improves neuro-cardiovascular regulation and prevents hyperalgesia in a mouse model of chronic widespread pain

R. Sabharwal[1], L. Rasmussen[2], K.A. Sluka[2] and M.W. Chapleau[1,3]

[1]Internal Medicine, University of Iowa, Iowa City, IA, USA, [2]Physical Therapy, University of Iowa, Iowa City, IA, USA and [3]Veterans Affairs Medical Center, Iowa City, IA, USA

Chronic widespread pain (CWP) as occurs in fibromyalgia is common and debilitating. Fibromyalgia is also associated with orthostatic intolerance, sleep disruption and fatigue. Autonomic nervous system dysfunction has been implicated in the etiology of this disease. Parasympathetic-mediated heart rate variability (HRV) is decreased in people with fibromyalgia with reports of increased sympathetic activity that could contribute to pain by sensitizing nociceptors. Exercise training has been shown to reduce pain in fibromyalgia. The aims of this study were to characterize autonomic dysregulation in an established mouse model of CWP [1], and determine if short duration (5-day) voluntary wheel-running influences neuro-cardiovascular regulation in either healthy or CWP mice. Blood pressure (BP)

and heart rate (HR) were measured by telemetry in conscious, young (10-12 wks) C57BL6 mice. CWP was induced by two intramuscular injections of acidic saline into the left gastrocnemius muscle (100 μl of sterile saline at pH 5, 5 days apart) under 2-5% isoflurane, combined with 2 hours of fatiguing exercise. CWP mice eat, drink, and groom normally, have normal gait patterns, and continue to gain weight similar to mice injected with pH 7.2 as a control (no hyperalgesia), or naïve animals [2]. CWP (hyperalgesia) was assessed by measuring the threshold for hindlimb withdrawal during application of a series of von Frey filaments to the paw. Data (mean±SEM) were analyzed using t-tests and repeated measures ANOVA as applicable, with significance taken at P<0.05 (see Table). Mice were killed with an overdose of pentobarbital at the end of the experiment. Induction of CWP decreased parasympathetic-mediated HRV (RMSSD) without affecting mean BP or sympathetic vasomotor tone measured by the depressor response to the ganglionic blocker chlorisondamine (Table, *P<0.05, CWP vs. Control, n=4-6). Five days of voluntary wheel-running decreased HR, BP and sympathetic tone measured at rest in healthy mice (*P<0.05, Exerc vs. Control) and mice subjected to induction of CWP (†P<0.05), and prevented both the decrease in HRV and secondary mechanical hyperalgesia in the ipsilateral paw (n=8) in CWP mice (†P<0.05, Exerc+CWP vs. CWP, n=4-8). We conclude: 1) This mouse model of CWP exhibits selective impairment of parasympathetic modulation of HR with preserved sympathetic vasomotor tone; and 2) Voluntary wheel-running decreases sympathetic tone, HR and BP in both healthy and CWP mice; and prevents hyperalgesia and decreased HRV in CWP mice. Future studies will explore the mechanisms underlying the beneficial effects of short-duration voluntary exercise.

Sustained hypoxia increases excitatory transmission in the nucleus tractus solitarius neurons of juvenile rats

D. Accorsi-Mendonça, C.L. Almado and B.H. Machado

Physiology, University of São Paulo, Ribeirão Preto, São Paulo, Brazil

In previous studies we verified that the synaptic transmission in the nucleus tractus solitarius (NTS) neurons is affected by chronic intermittent hypoxia. Here we evaluated the effect of short-term sustained hypoxia (SH, 24 hours - 10% O2) on the intrinsic properties and synaptic transmission of NTS neurons in the brainstem slices from young rats (3 weeks old) using whole cell patch clamp technique. SH produced no change in resting membrane potential [control: -78.7 ± 2.4 mV (n=15), SH: -72.3 ± 3.7 mV, (n=15)], input resistance [control: 1.4 ± 0.4 GOhm (n=8), SH: 1.4 ± 0.4 GOhm, (n=9)] and capacitance of NTS neurons [control: 14.2 ± 0.9 pF (n=17), SH: 12.4 ± 0.8 pF (n=15)]. However, SH increased the frequency of spontaneous excitatory post-synaptic currents [(sEPSCs) control: 3.6 ± 0.4 Hz (n=18), SH: 7 ± 1.5 pF, (n=15), p<0.05] and the amplitude of evoked excitatory post-synaptic currents [(eEPSCs) control: -289 ± 51 pA (n=15), SH: -472 ± 64 pA (n=15), p<0.05]. Moreover, SH also increased the depression of evoked excitatory post-synaptic currents after five stimuli on afferent fibers in the tractus solitarius [amplitude of 5 evoked currents of control group: 100%, 44%, 34%, 32% and 28% (n=15), amplitude of 5 evoked currents of SH group: 100%, 40%, 28%, 22% and 17% (n=15) *p<0,001 - Two way ANOVA]. These findings suggest that SH affect the excitatory transmission in NTS neurons increasing the release probability in the pre-synaptic terminal. We conclude that 24 hours of SH enhances spontaneous and evoked excitatory synaptic transmission on NTS neurons but does not change their intrinsic properties. These alterations in the synaptic transmission in the NTS neurons induced by SH may play a critical role in the cardiovascular and respiratory problems observed in high altitude.

PCA118

Catecholamines in the medial prefrontal cortex and nucleus accumbens alter cardiorespiratory and metabolic functions

A. Goodchild[1], S.F. Hassan[1] and J.L. Cornish[2]

[1]The Australian School of Advanced Medicine, Macquarie University, Sydney, NSW, Australia and [2]Dept Psychology, Macquarie University, Sydney, NSW, Australia

Purpose: Methamphetamine (METH) blocks and reverses monoamine transporters and its administration evokes behavioural changes associated with frontal brain regions. METH also evokes autonomic effects. We have shown that disinhibition of the medial prefrontal cortex (mPFC) changes cardiorespiratory and metabolic function. We sought to determine whether alterations in monoamine concentrations in the mPFC and nucleus accumbens (NAc) mediate changes in cardiorespiratory and metabolic function. Methods: Electrophysiological experiments were performed in urethane-anaesthetised, artificially ventilated, vagotomised, male Sprague-Dawley rats. Microinjections of METH (35, 105, 335 nmol), dopamine hydrochloride (DA 10, 50,150, 475 nmol) or L-norepinephrine (NA 10, 50, 150 nmol) were made into the infralimbic cortex of the mPFC and NAc. Changes were recorded in iBAT, heart rate (HR), expired CO2, phrenic nerve amplitude and frequency (PNamp and PNf), mean arterial pressure (MAP), splanchnic and lumbar sympathetic nerve activity. Results: METH in PFC evoked respiratory depression at low doses but increased all parameters at high doses. DA evoked increases in thermogenic and metabolic outflows (iBAT;2.2±0.3 deg C, HR;21±4bpm and expired CO2;0.67±0.11% (n=5)) and in respiratory function (PNf;11±1bpm, and, PNamp;137±15% (n=5)) with little change in other parameters only at the highest dose with only respiratory depression evoked at low doses. In contrast in the PFC NA evoked dose dependent increases in MAP (18±2mmHg, 10ug/kg, n=5), iBAT (0.8±0.15 degC), HR (16±2bpm) and expired CO2 (0.35±0.07%) and respiratory function. Conclusions: In PFC respiratory depressant effects were evoked by low doses of METH and these were mimicked by low doses of DA. The increased cardiovascular, respiratory

and metabolic function evoked by METH in PFC was mimicked by NA, although DA may also contribute. Alteration in monoamine levels in frontal brain regions alters cardiorespiratory and metabolic function.

The inflammatory response in the spontaneously hypertensive rat: Effects of anti-hypertensive interventions

P.J. Marvar, F.D. McBryde and J.F. Paton

Physiology and Pharmacology, University of Bristol, Bristol, UK

Previous studies have found inflammation, in particular T lymphocytes, to be a contributing factor in the genesis of various forms experimental hypertension (1,2). Currently, clinical interventions such as renal denervation (RD) and carotid body denervation (CBD) are aimed at targeting the autonomic nervous system to treat hypertension (3). However, the effects of these blood pressure lowering strategies on the immune system are unknown. In the current study, RD and CBD was performed in the spontaneously hypertensive rat (SHR) and flow cytometry used to examine tissue infiltration of T lymphocytes (CD3+) in the aorta and brainstem.

All procedures conformed to the UK Home Office guidelines on animals (Scientific Procedures) Act 1986 and were approved by the University of Bristol's Animal Ethic Committee. Rats were anaesthetised with ketamine (60 mg kg–1; i.m.) and medetomidine (250 μg kg–1, i.m.) and aseptic techniques used. Bilateral RD was achieved via a retroperitoneal incision to exposure of the renal artery. The nerves and adventitia were stripped from the renal artery and renal plexus, which were then painted with a dilute (10%) phenol solution. For CBD, the CB was visualised and branches of the carotid sinus nerve sectioned. Surgical sham-operated SHR (SS) rats underwent the same surgical procedures to expose the kidney and CB but the nerves were left intact. Compared to the SS group, arterial pressure and renal sympathetic nerve activity in the SHR was significantly lowered following both RD and CBD (see abstract by W. Pijacka et al). The percentage of infiltrating CD3+ T lymphocytes in the brainstem (9.6 ± 0.7 vs 6.4 ± 0.8%; $t(9) = 2.79$, $p < 0.05$) as well as the aorta (14.5 ± 1.6 vs 10.0 ± 1.1%; $t(16) = 2.18$, $p < 0.05$) were significantly reduced following RD. Following CBD, there was a trend toward reduced percentage of CD3+ cells in the aorta ($t(13) = 1.36$, $p = 0.19$) but unlike RD, there was no change in CD3+ cells in the brainstem. These data suggest that there is significant systemic CD3+ cell infiltration in the SHR and that some, but not all, procedures targeting the autonomic nervous system may have benefits in lowering tissue inflammation associated with hypertension. We strive to determine the causal relationship between reduced vascular inflammation and the anti-hypertensive effect of RD.

The role of glucocorticoid receptors within the Basolateral Amygdala on the alteration in morphine-induced conditioned place preference following swim stress

G. Attarzadeh Yazdi[1], S. Yazdi-Ravandi[2], S. Karimi[2] and A. Haghparast[2]

[1]Physiology, Hormozgan University of Medical Sciences, Bandar abbas, Islamic Republic of Iran and [2]Neuroscience Research Center, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran

Stress represents a wide range of physical responses and plays an important role in modulating different stages of memory including reconsolidation. Relapse to drug taking induced by exposure to stimuli or cues associated with drugs of abuse is a main challenge to the treatment of morphine addiction. It has been shown that drug seeking can be inhibited by disrupting the reconsolidation of a drug-related memory, but, the effect of glucocorticoid receptors in Basolateral Amygdala on the alteration in morphine-induced conditioned place preference following swim stress has not been fully studied. We examined the effects of forced swim stress (FFS) and corticosterone on reconsolidation of a drug-related memory using a conditioned place preference (CPP) procedure.

Male adult rats received FSS as a physical stress or corticosterone (10 mg/kg; ip) as a dominant stress hormone in rodents, 10 min before injection of morphine (5 mg/kg; sc), during 3 conditioning days (acquisition) or just prior to CPP test in the post-conditioning day (expression). In FSS procedure, animals were forced to swim for 6 min in cylinder filled with water (24-27 ^{o}C).

All animals underwent extinction sessions until the CPP was extinguished; rats were confined to the previous morphine- or saline-paired compartment for 30 min a day for 8 days. The next day following the last extinction session, morphine CPP reinstatement was induced by FSS as stress-induced reinstatement.

The results showed that animals acquired morphine CPP after conditioning, and that this CPP was inhibited by stress given immediately after re-exposure to morphine. Corticosterone injection which leads to immediate and sudden increase in the level of glucocorticoids fails to reinstate the terminated CPP in rats. Studies on FSS-induced reinstatement show that this behavior is blocked by administration of corticotropin-releasing hormone (CRH) antagonists. Overall, these results suggest that corticosterone plays an important role in relapse to drug seeking behavior induced by stress.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA121

ATP-mediated signalling in the pre-sympathetic area of the brainstem is critical for the development of hypertension in spontaneously hypertensive rats

R. Ang[1], N. Marina[1], S. Kasparov[2] and A.V. Gourine[1]

[1]University College London, London, UK and [2]Bristol University, Bristol, UK

Introduction
Increased sympathetic drive is associated with the development and progression of essential hypertension. Pharmacological studies have shown a direct stimulatory effect of ATP on bulbospinal sympathoexcitatory (pre-sympathetic) neurones of the rostral ventrolateral medulla oblongata (RVLM), leading to marked increases in sympathetic nerve activity and arterial blood pressure (1). Astroglial cells of the RVLM contribute to a significant ATP tone in this area of the brain (2). The aim of this study was to determine whether ATP actions within the RVLM contribute to the control of arterial blood pressure in normotensive and hypertensive rats.
Methods
We developed a lentiviral vector (LVV) to drive the expression of a potent membrane-bound ectonucleotidase – transmembrane prostatic acid phosphatase (TMPAP) for facilitated breakdown of extracellular ATP. LVV-TMPAP or control LVV-GFP were injected stereotaxically into the RVLM of pre-hypertensive (8-weeks-old) spontaneously hypertensive rats (SHRs) and age-matched Wistar rats anaesthetised with a mixture of ketamine (60mg/kg, im) and medetomidine (250μg/kg, im). Anaesthesia was reversed with atipamezole (1mg/kg, im). Blood pressure measurements were commenced 1 week after the injections and repeated weekly for 4 weeks by occlusive tail cuff method in conscious rats. Data is expressed as mean ± SEM and one-way ANOVA was used to assess statistical significance.
Results
Expression of TMPAP in the RVLM of SHRs resulted in a significant reduction in arterial blood pressure. Three weeks after the injections, SHRs transduced to express TMPAP in the RVLM had mean arterial blood pressure of 115.6±8.8 mmHg (n=7), which was significantly (p=0.009) lower than that in SHRs transduced to express GFP (152.9±8.4 mmHg, n=9). In comparison, TMPAP expression in the RVLM had no significant effect on the mean arterial blood pressure of control Wistar rats (91.4±4.5 vs 92.6±3.5 mmHg, p=0.836, n=8 in both groups).
Conclusion
Increased breakdown of extracellular ATP in the brainstem area where the key sympathoexcitatory neurones reside reduces the degree of hypertension in the SHR. These data suggest that ATP-mediated signalling has a significant impact on brain pre-sympathetic circuits and appears to be critical for the development of essential hypertension.

PCA122

Evaluation of hypothalamic neuropeptides and inflammatory factors correlated to blood pressure changes in high fat diet-induced obesity in mice

L.J. Chaar, I.M. Ribeiro, N.M. Silva, W.T. Festuccia and V.R. Antunes

Department of Physiology and Biophysics, Institute of Biomedical Sciences, University of Sao Paulo, Sao Paulo, SP, Brazil

Obesity is a worldwide epidemic and a risk factor for cardiovascular diseases, and it is associated with a sympathetic overactivation to different organs that could be involved in obesity-associated hypertension. Moreover, it has been shown that the hypothalamic inflammation induced by high fat diet can alter the neurotransmission of autonomic centers leading to increases in the blood pressure. Here we screened the hypothalamus of diet-induced obesity in mice for neuropeptides and inflammatory factors that could be involved in the changes in mean arterial pressure (MAP) associated with obesity. Male mice C57BL6 submitted to high fat (HF; 60%kcal lipids) or control (C) diet for 8 weeks were evaluated for body weight gain, glucose tolerance, adiposity and plasma levels of leptin, insulin, triglycerides and free fatty acids. Femoral catheterization was performed under anesthesia with isoflurane (5% in O2-air inspired) and MAP was recorded in conscious freely moving mice. Hypothalamic mRNA of inflammation mediators and neuropeptides were quantified by qPCR. Values are expressed as mean±S.E.M., compared by ANOVA or t-Test; $p<0.05$. HF mice developed obesity as evidenced by the increased body weight gain (31%) and adiposity (epididymal, retroperitoneal and inguinal fat depots) in comparison to C group. Furthermore, HF diet increased fasting plasma levels of glucose (C: 177±8 vs HF: 200±6 mg/dL); leptin (C: 8±3 vs HF: 17±5 ug/ml), insulin (C: 43±7 vs HF: 672±127 pmol/L), triglycerides (C: 1.0±0.4 vs HF: 2.2±0.6 mmol/L), free fatty acids (C: 0.2±0.1 vs HF: 0.7±0.2 nmol/L), and induced severe glucose intolerance (C: 24106 vs HF: 35170 u.a., $p<0,0001$). The HF-diet led to two different hemodynamic phenotypes: obese hypertensive (OH: 123±2 mmHg, n=2) and obese resistant hypertension (OR: 102±5 mmHg, n=3) when compared with group C (107±1 mmHg, n=3). The MAP showed strong correlation with the glucose intolerance (r2 = 1.0, n=3). In addition, the HF-diet elicited an increase of the hypothalamic mRNA levels of cocaine- and amphetamine-regulated transcript (CART, +69%, n=5), decreased agouti gene-related peptide (AgRP, -52%, n=5) and interleukin-6 (IL-6, -40%, n=5) when compared to the C group. Our data have shown that high fat diet affected MAP and others obesity-related metabolic changes, such as glucose intolerance, hyperinsulinemia, dyslipidemia, hyperleptinemia, insulin resistance and altered mRNA levels of neuropeptides involved in the regulation of energy balance (CART and AgRP) and cytokines (IL-6) at the hypothalamus level. In fact, there is a great correlation between increasing in MAP and glucose tolerance, that could be also has a causality relationship with changes in neuropeptides and inflammatory factors in the autonomic nucleus of the hypothalamus that control blood pressure.

PCA123

Transgenic Sprague Dawley rats with ataxin3-mediated destruction of orexin neurons display reduced tail artery Sympathetic Cutaneous Vasomotor Alerting Responses (SCVARs)

M. Mohammed[1], Y. Ootsuka[1], M. Yanagisawa[2] and B. Blessing[1]

[1]Human Physiology, Flinders University, Adelaide, SA, Australia and [2]Department of Molecular Genetics, University of Texas Southwestern Medical Centre, Dallas, TX, USA

Orexin neurons, located in perifornical hypothalamus (de lecea et al., 1998; Sakurai et al., 1998), influence appetite, the sleep-wake cycle, locomotor activity as well as a number of physiological variables. Transgenic mice with ataxin3-mediated destruction of orexin neurons have attenuated thermogenic and other autonomic responses to arousing environmental stimuli (Zhang et al., 2010), but constriction of the tail artery in response to alerting stimuli has not been assessed in animals in which orexin-containing neurons have been selectively destroyed. We have now assessed sympathetic cutaneous vasomotor alerting responses (SCVARs, de Menezes et al., 2009) in the tail artery of conscious unrestrained transgenic Sprague Dawley rats with ataxin3-mediated destruction of orexin neurons (Beuckmann et al., 2004), in comparison with wildtype control animals. Under inhaled isoflurane (2% in oxygen) anaesthesia, transgenic (n=10) and wildtype (n=8) male rats (300-450 g) were instrumented with ultrasound Doppler flow probes (Iowa Inc, USA) chronically implanted around base of the tail artery. All surgical procedures were performed in accord with the Animal Welfare Ethics Committee of Flinders University. Tail probe cables were passed subcutaneously and connected to a headpiece fixed to the skull with dental cement. After one-week recovery unrestrained rats were placed in a quiet closed wooden box at 24-26°C. The tail artery blood flow signal (40 Hz sampling rate) was recorded, via a swivel device, with PowerLab (ADInstruments). We administered standardized alerting stimuli (salient but not stressful) and assessed the acute effect on blood flow in the tail artery, calculated as the percentage change in flow induced by the stimulus (SCVAR index). Group SCVAR results (mean ± SEM) were analysed with factorial ANOVA. The SCVAR index in transgenic rats was 69 ±2%, significantly less than 84±2% ($p<0.001$), the corresponding wildtype value. Immunohistochemical examination of the perifornical area of the hypothalamus documented complete absence or substantial loss of orexin-containing neurons in the transgenic rats. Our findings support the view that the orexin-containing neurons function to increase the physiological response to the animal's perception of salient, potentially threatening environmental events.

PCA124

Co-localisation of the neurotransmitter synthesising enzymes GAD67 and choline acetyltransferase in the mouse nucleus tractus solitarius

J. Gotts, I.J. Edwards, S.A. Deuchars and J. Deuchars

University of Leeds, Leeds, UK

The nucleus of tractus solitarius (NTS) is the main integration site for autonomic control. It receives afferent information from arterial baroreceptors, chemoreceptors, cardiac receptors, gastrointestinal receptors and respiratory receptors (1). Details on the neurochemical properties of NTS neurones have been established by many researchers. However information on the co-localisation of choline acetyltransferase (ChAT) and glutamic acid decarboxylase (GAD) immunoreactivity within the NTS has not been reported. This study examined the distribution of ChAT immunoreactivity and co-localisation with green fluorescent protein (GFP) in the NTS of transgenic mice (n=4) expressing GFP under control of the GAD67 promoter (GAD67-GFP mice) (2) using fluorescence immunohistochemistry (3).

Four GAD67-GFP adult mice (mixed sexes) were injected intraperitoneally with 1 % Fluorogold. After 24-48 hours the mice were anaesthetised with 60 mg/kg sodium pentobarbitone and when the withdrawal reflex was absent, they were perfused transcardially with 4 % paraformaldehyde. The brainstems were postfixed with 4 % paraformaldehyde for 24 hours. Brainstems were sectioned (at 50 μm and 30 μm for double and triple labelling respectively). Serial sections were processed utilising fluorescent immunohistochemistry (IHC). One wild type adult mouse was also prepared in the same way as the GAD67-GFP mice. Sections were processed using diaminobenzidine IHC for ChAT to provide a permanent reaction product. ChAT immunoreactive (ChAT-IR) and GAD67-GFP immunoreactive (GAD67-GFP-IR) neurones were found in all NTS subnuclei. Moreover, co-localisation was observed in some NTS subnuclei; predominantly in the intermediate subnucleus (co-localised neurones per section were 6.83 ± 1.89 (mean ± SEM) for the right and 6.67 ± 2.19 for the left NTS column, n = 6 sections) and the central subnucleus (1.00 ± 0.68 (right NTS) and 2.17 ± 1.42 (left NTS)). Nitric oxide synthase immunoreactive (nNOS-IR) neurones in the central subnucleus are reported to be involved in oesophageal regulation (4). In our study, although nNOS-IR neurones were prominent in the central subnucleus, they did not exhibit co-localisation with either ChAT or GAD67-GFP. Although the absence of co-labelling in the central subnucleus with nNOS does not support a role for ChAT/GAD-IR neurones in oesophageal control, this possible

function cannot be excluded at this time. Examination of other brainstem areas revealed co-localisation of ChAT and GAD67-GFP immunoreactivity, including the area postrema, the reticular formation and the lateral paragigantocellular nucleus. Since there is limited information of co-localisation for ChAT and GAD immunoreactivity in the brainstem, it is worth studying further to investigate its roles in these neurones.

PCA125

The properties and synaptic inputs of cholinergic interneurones

V.K. Lall, I. Edwards, J. Deuchars and S. Deuchars

School of Biomedical Sciences, University of Leeds, Leeds, UK

The central autonomic area (CAA) contains interneurones which directly influence sympathetic preganglionic neurones (Deuchars et al., 2005). Sensory afferent terminals are located around lamina X and form close appositions with interneurones (Hofstetter et al., 2005). CAA neurones have been identified as being premotor to somatic motor neurones (Stepien et al., 2010). This suggests that these interneurones may coordinate autonomic and motor outflow from the spinal cord and therefore, may receive inputs from primary afferents. This study aims to address how these interneurones fit into circuits involved in autonomic control. To investigate whether interneurones in CAA received direct inputs from myelinated primary afferents, immunohistochemistry for vesicular glutamate transporter 1 (VGLUT1) was conducted in GAD67-GFP mice anaesthetised with pentobarbital (60mg/kg; i.p) and transcardially perfused with 4% paraformaldehyde. Close appositions were observed between VGLUT1 primary afferent terminals and interneurones immunoreactive for GFP (GABAergic) or Choline Acetyltransferase. To determine how interneurones responded to stimulation at the dorsal root entry zone, 7-12 day old mice and 12-21 day old rats, of either sex, were anaesthetised by urethane (2g/kg; i.p). Transcardiac perfusion was followed by decapitation and 300μm transverse slices of lumbar and thoracic spinal cord were cut. Viable interneurones in laminae VII and X were identified and whole cell patch clamp recordings performed. A stimulating electrode was placed at the dorsal root entry zone to deliver stimuli (5-100 Hz) of 1 ms duration. The evoked excitatory postsynaptic potential (EPSP) amplitude was recorded and the latency to onset of the EPSP measured. The standard deviation (SD) of latency gave an indication of variability in latency (jitter). Values are means ± S.E.M, compared by 2 sample t-test. Mouse thoracic interneurones had an action potential threshold of -35.06 ± 1.99 mV, action potential amplitude of 49.52 ± 2.64 mV and afterhyperpolarisation amplitude of -19.45 ± 1.08 mv (n= 15). EPSP jitter was 2.31± 0.01 μs (n= 7). EPSPs followed high frequency tetanic stimulation, without failures indicating that they are likely elicited by monosynaptic primary afferents, and were significantly antagonised by 20 μM NBQX (an excitatory amino acid receptor antagonist) (7.68 ± 0.64 mV in control (n= 7) to 3.28 ± 0.45 mV (n= 7) in NBQX; p< 0.001). In rats, EPSP jitter was 4.23 ± 0.51 μs (n= 16) and EPSP amplitude was significantly reduced with NBQX (6.43 ± 0.04 mV (n= 16) in control to 0.42 ± 0.24 mV (n= 9) in 20 μM NBQX; p< 0.001). Post hoc analysis revealed extensive axon ramifications in both the dorsal and ventral horn. The direct action of primary afferents onto interneurones in the CAA may provide a avenue for the co-ordination of autonomic and motor activity.

Redox-sensitive endoplasmic reticulum stress and autophagy at rostral ventrolateral medulla contribute to hypertension in SHR

Y. Chao[1,2] and J. Chan[2]

[1]Institute of Basic Medical Sciences, National Cheng Kung University, Tainan, Taiwan and [2]Center for Translational Research in Biomedical Sciences, Chang Gung Memorial Hospital-Kaohsiung Medical Center, Kaohsiung, Taiwan

Perturbations of proper functions of the endoplasmic reticulum (ER) cause accumulation of misfolded or unfolded proteins in the cell, creating a condition known as ER stress. Prolonged ER stress has been implicated in hypertension. Oxidative stress in the rostral ventrolateral medulla (RVLM), where sympathetic premotor neurons for the maintenance of vasomotor tone reside, plays a pivotal role in neurogenic hypertension. This study aimed to evaluate the contribution of ER stress in RVLM to oxidative stress-associated hypertension, and delineated the underlying molecular mechanisms. The expression of glucose-regulated protein 78 kDa (GRP78) and phosphorylation of protein kinase RNA-like ER kinase-translation initiation factor α (p-eIF2α), two major protein markers of ER stress, were augmented in RVLM and preceded the development of hypertensive phenotype in spontaneously hypertensive rats (SHR). In RVLM of SHR, stabilizing ER stress by salubrinal promoted antihypertension, and scavenging the reactive oxygen species by tempol reduced the augmented ER stress. Furthermore, induction of oxidative stress by angiotensin II induced ER stress in RVLM, and induction of ER stress by tunicamycin in RVLM induced pressor response in normotensive Wistar-Kyoto rats. Autophagy, as reflected by the expression of lysosome-associated membrane protein-2 and microtubule-associated protein 1 light chain 3-II (LC3-II), was significantly increased in RVLM of SHR, and was abrogated by salubrinal. In addition, inhibition of autophagy or silencing LC3-II gene in RVLM resulted in antihypertension in SHR. These results suggest that redox-sensitive induction of ER stress and activation of autophagy in RVLM contribute to oxidative stress-associated neurogenic hypertension.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Low extracellular pH leads to free radical formation and mitochondria depolarization in rat brain synaptosomes

S.V. Fedorovich, T. Pekun, V. Lemeshchenko and T. Waseem

Institute of Biophysics and Cell Engineering, Minsk, Belarus

Brain ischemia is accompanied by lowering of intra- and extracellular pH down to 6.5 in the case of hyperglycemia, even down to pH 5.3. It has been shown that stroke often leads to irreversible damage of synaptic transmission. The mechanism of this phenomenon is still not clear. We investigated an influence of lowering of intra- and extracellular pH on free radical formation in synaptosomes, isolated neuronal presynaptic endings. We have used three model of acidosis. 1) Strong extracellular acidification down to pHo 6.0 corresponding to pHi decrease from 7.15 down to 6.04. 2) Moderate extracellular acidification down to pHo 7.0 corresponding to the lowering of pHi down to 6.92. 3) Intracellular acidification induced by addition of 1 mM amiloride corresponding to pHi decrease down to 6.65. We have shown that both types of extracellular acidification, but not intracellular acidification, increase DCFDA fluorescence that reflects reactive oxygen species formation. These three treatments induce the rise of the dihydroethidium fluorescence that reports synthesis of superoxide anion in synaptosomes. However, the impact of intracellular acidification on superoxide anion synthesis was less than that induced by moderate extracellular acidification, although 1 mM amiloride decreases the internal pH more strongly than lowering of extracellular pHo down to 7.0. Mitochondrial uncoupler CCCP (10 μM) and NADPH oxidase inhibitor DPI (30 μM) did not inhibit an increase of fluorescence of both dyes at pHo 6.0. In contrast, superoxide anion synthesis at pHo 7.0 was almost completely eliminated by CCCP, hence not affecting an increase of DCFDA fluorescence. Furthermore, using fluorescent dyes JC-1 and rhodamine-123, we confirmed that extracellular pH lowering, including pHo 7.0, but not intracellular acidification led to depolarization of intrasynaptosomal mitochondria. Assumingly, for moderate extracellular acidification the following chain of events is thought to be probable: proton binding to non-identified receptors, localized on the plasma membrane of neuronal terminals triggers transduction of the signal to the mitochondria where the superoxide anion radical is synthesized and then initiates the development of the oxidative stress. Action of strong extracellular acidification seems to be mediated by an inhibition of antioxidant enzymes and release of iron from proteins.
We have shown that pHo lowering led to oxidative stress in neuronal presynaptic endings that might underlie the long term irreversible changing in synaptic transmission.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA128

Electrophysiological characteristics of newborn cells in the adult mouse midbrain

A. Dey and T. Aumann

Neurodegeneration, Florey Institute for Neuroscience & Mental Health, Melbourne, VIC, Australia

Background: Parkinson's Disease (PD) is the second most common neurodegenerative disorder in the aging population. Cardinal motor symptoms include slowness of movement, muscle rigidity, tremor and postural instability; caused by death of dopamine cells in the substantia nigra pars compacta (SNpc) of the midbrain. Traditional treatment regimes include administration of levodopa, or dopamine receptor agonists. However these produce side-effects and eventually fail in most patients within 5-10 years [1]. Advances in cell transplantation therapies have shown promising results in alleviation of motor symptoms [2] by providing targeted dopamine delivery. However, several problems need to be overcome for more effective outcomes to be achieved, including; acquisition and maintenance of the dopamine phenotype and integration into the adult midbrain. This is best overcome by learning how new dopamine neurons are normally generated in the adult midbrain.
Purpose and Methods: Characterise the electrophysiology of newborn cells in the NesCreERT2/GtROSA+\+ mouse as they proliferate, migrate and differentiate into dopamine neurons; using whole-cell patch clamping techniques.
Results: Recordings were made from regions of the adult midbrain including; lining of the cerebroventricular aqueduct, periaqueduct grey (PAG), ventral midline, ventral tegmental area (VTA) and SNpc. Cells displayed a variety of electrophysiological profiles from relatively immature to fully mature neuronal phenotypes. Cells lining the aqueduct exhibited a relatively negative resting membrane potential (n=15,-76.7±1.2mV), small capacitance (6.0±1pF), no action potentials or synaptic activity. In addition they had no apparent voltage-sensitive conductances, typical of an astrocyte like phenotype. YFP+ cells in the PAG (n=8) exhibited a slightly more mature neuronal phenotype with some evidence of voltage-sensitive conductances and larger capacitance values (12.9±4.3pF). They exhibited spontaneous post-synaptic currents (sPSC) in 25% of cells, indicating receipt of synaptic input from other neurons, although only exhibited action potentials in 50% of cells, in contrast to cells in the midline, VTA and SNpc which had actions potentials in all cells. YFP+ cells in the ventral midline through to the SNpc had larger amplitude (midline: 53.4±4.3mV (n=15), VTA: 57.3±3.7mV (n=7), SNpc: 50.2±4.1 (n=9)) and shorter duration (midline: 1.3±0.3ms (n=15), VTA: 1.1±0.2ms (n=7), SNpc: 1.3±0.3ms (n=9)) action potentials, than the aqueduct or PAG region. Finally, YFP+ cells along this gradient also displayed sPSCs in 47% of cells in the ventral midline and 25% of cells in the VTA and 33% in the SNpc.
Conclusion: Electrophysiology indicate cells appear to be transitioning from precursors to neurons from the cerebral aqueduct to the SNpc, possibly indicating integration of these new born cells into the dopamine system.

Fructose increases ATP-and ROS-dependent neurotransmitter release

K. Wu, S.H. Chan and J.Y. Chan

Center for Translational Research in Biomedical Sciences, Chang Gung Memorial Hosptial, Kaohsiung, Taiwan

High fructose consumption induces increases in sympathetic nerve activity, although the underlying cellular mechanism is not fully understood. ATP is essential for neuronal activity. We verified in the present study the hypothesis that fructose directly increases ATP production in catecholamine-containing neuron to cause the release of neurotransmitter. Application of different concentrations of fructose (12.5, 25, 50 or 100 μmole/L) to the mouse neuroblastama N2A cells for 3 days resulted in a dose-related increase in ATP production in the cell. In addition, reactive oxygen species (ROS) production was also significantly increased in a dose-dependent manner. Oxygen consumption rate and proton production of mitochondria were significantly increased under high fructose status. Dopamine level in the medium was increased in N2A cells exposed to fructose. The expression of tyrosine hydroxylase and surface expression of dopamine transporter were also significantly increased. Moreover, expression of glutamate transporter 2 (GLUT2), a fructose transport, was significantly increased in response to fructose treatment. Down-regulation of GLUT2 by transfection of Glut2 siRNA effectively suppressed the induced GLUT2 expression and attenuated fructose-promoted ATP and ROS production, and dopamine secretion from the N2A cells. The fructose-induced dopamine secretion was also blunted by scavenging ROS with mitoTEMPO. Together our data indicated that fructose may directly increases neuronal activity through increase in ATP and ROS production via activation of GLUT2.

PCA130

Neuroprotective anti-oxidant effect of a Nitric Oxide synthase inhibitor in cerebral injury induced by transient focal ischemia/ reperfusion in rats

A.M. Saeed[1], H.A. Awooda[2] and G. Sharara[3]

[1]Physiology, University of Khartoum, Khartoum, Khartoum, Sudan, [2]Physiology, Alneelain University, Khartoum, Sudan and [3]Biochemistry, Alexandria University, Alexandria, Egypt

Background: Reports assessing the neuroprotective role of nonselective NO synthase (NOS) inhibitors following cerebral ischemia/reperfusion are contradictory (1-2). Aims: To examine the potential benefits of N-nitro-L-arginine-methylester (L-NAME) on rats subjected to transient focal cerebral ischemia/reperfusion. Materials and methods: The study involved three groups of males adult Wister rat each consist of 10: a control group operated at the neck region without occlusion of left common carotid artery (CCA), a placebo group infused with 0.9% normal saline intraperitoneally 15 minutes prior to left cerebral ischemia/reperfusion induced by transient (30 minutes) left CCA occlusion and a test group infused with L-NAME intraperitoneally 15 minutes prior left cerebral ischemia/reperfusion (3). Anesthesia was induced by ether inhalation and maintained by thiopental sodium (2.5mg/kg). Malondialdehyde (MDA), NO metabolites and total antioxidant capacity (TAC) in serum and the affected cerebral hemisphere were measured. Neurobehavioral deficits were evaluated. Results: The neurological deficit of both placebo and test groups were significantly lower compared to the control group. The test group showed a significant improvement in neurological deficit compared to the placebo group (P <0.001).The placebo group demonstrated a significant increase in the serum levels of both MDA and NO (14.88±1.14 nmol/mL, 42.03±4.56 μmol/L respectively) compared to the control group (5.43±0.44 nmol/mL, 17.84±0.7 μmol/L respectively, P <0.001). Values are means ± S.E.M., compared by ANOVA. Alternatively, the test group showed significant decrease in serum level of MDA and NO (7.18±0.13, 18.44±0.51μmol/L respectively, P <0.001) compared to the placebo group. The serum level of TAC in the placebo group (1.21±0.17 mM/L) was significantly lower compared to the control group (2.52±0.06 mM/L, P <0.001) but not the test group (2.53±0.067mM/L). L-NAME pretreatment resulted in significant higher serum level of TAC compare to placebo group (P <0.001).The brain tissue levels of MDA and NO of the placebo group (8.56±0.7, 8.88±0.57 nmol/mg protein) was significantly higher than the control group (3.24±0.22, 3.48±0.22 nmol/mg protein, P <0.001). The test group showed a significant decrease in tissue level of MDA and NO (3.18±0.1, 4.47±0.4 nmol/mg protein, P <0.001) compared to the placebo group. Administration of L-NAME prior to ischemia result in significant increase of brain TAC level compare to placebo (0.07±0.009 vs 0.02±0.004 mmol/mg protein P < 0.001). Conclusions: L-NAME pretreatment for rats undergoing cerebral ischemia/reperfusion significantly improve neurological deficit through reducing oxidative stress biomarkers in the affected cerebral hemisphere.

Neuroprotective effects of Lycium barbarum polysaccharides in lipopolysaccharide-induced BV2 microglia cells

Y. Wang[1], Y. Li[1], P. Teng[1], X. Hou[2], L. Wang[2], Q. Qi[1], L. Zhou[3], Y. Shen[3], Y. Zhang[1] and Z. Miao[1]

[1]Ningxia Medical University, Yinchuan, China, [2]General Hospital of Ningxia Medical University, Yinchuan, China and [3]Zhejiang University, Hangzhou, China

Polysaccharides, extracted from Lycium barbarum (LBPs), display a wide variety of biological activities. However, the neuroprotective effects of LBPs remain poorly understood. The present study aimed to investigate the inhibitory effects of LBPs on production of lipopolysaccharide (LPS)–induced pro-inflammatory mediators in BV2 microglia. Our data showed that LPS induced the activation of NFκB and its upstream caspase 3 and upregulated the expression of another apoptosis-inducing factor, HSP60 in BV2 microglia cells and increased the release of TNF-α and HSP60 in culture media. After LBPs treatment, activated NFκB and caspase 3 were significantly suppressed. The enhanced expression of HSP60 was reduced and LPS induced release of TNF-α and HSP60 were inhibited. These results suggest that LBPs may offer substantial therapeutic potential for treatment of neurodegenerative diseases that are accompanied by microglia activation.

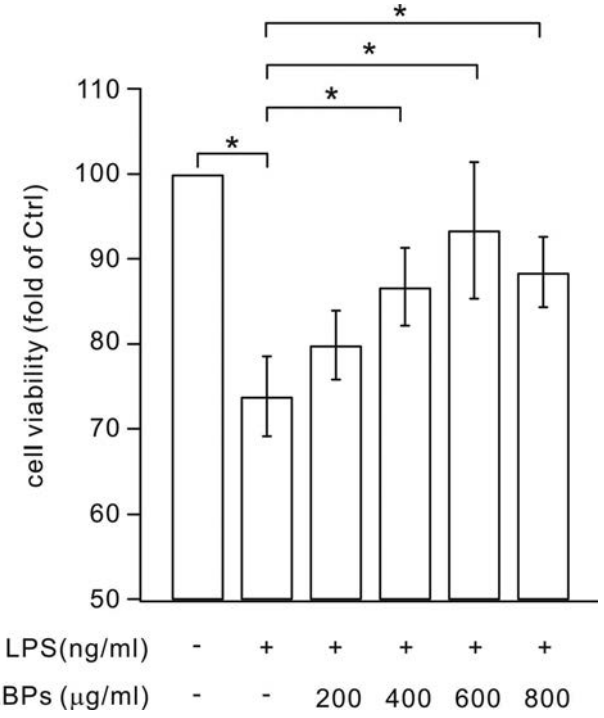

Figure 1. LBPs increase the cell viability of BV2 microglia. BV2 cells were treated with LPS (200 ng/ml) for 1 h and then treated with various concentrations of LBPs (0, 200, 400, 600, or 800 μg/ml) for 24 h. The viability of LPS and LBPs-untreated cells was set to 100. The viability of LPS and LBPs-treated cells was expressed as the percentage of the untreated cells. Results were obtained from 3 independent experiments. *, P <0.05.

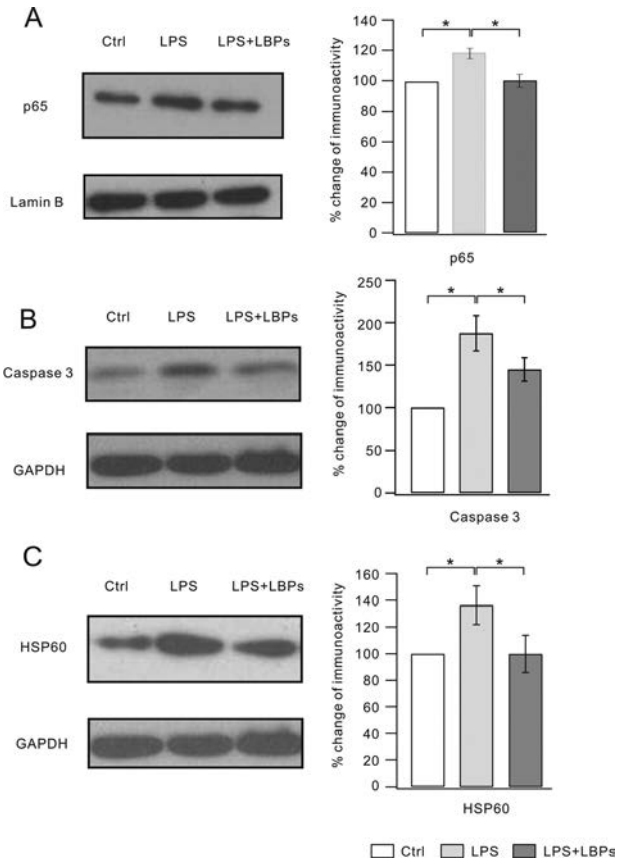

Figure 2. LBPs inhibit the increased expression of NFκB, caspase-3 and HSP60 in LPS-stimulated BV2 microglia. Cells were pre-treated with LPS for 1 h and then incubated with 600 μg/ml LBPs for 24 h. (A) The lysates were probed by immunoblotting with antibodies to p65 and lamin B. The right panel shows ratios of signal intensity of p65/lamin B (Ctrl: 100%; LPS: 119.3±7%; LPS+LBP: 107.3±9%). (B) The lysates were probed by immunoblotting with antibodies to caspase-3 and GAPDH. The right panel shows ratios of signal intensity of caspase-3/ GAPDH (Ctrl: 100%; LPS: 187.4±20.8%; LPS+LBP: 144.9±13.7%). (C) The lysates were probed by immunoblotting with antibodies to HSP60 and GAPDH. The right panel shows ratios of signal intensity of HSP60/GAPDH (Ctrl: 100%; LPS: 136.5±14.4%; LPS+LBP:100±18%). Each experiment was derived from 10 independent cultures. *, P <0.05.

PCA133

Peptide hormone ghrelin enhances neuronal excitability by inhibition of Kv7/KCNQ channels

L. Shi[1], X. Bian[2], Z. Qu[1], Z. Ma[1], Y. Zhou[1], K. Wang[2], H. Jiang[1] and J. Xie[1]

[1]Department of Physiology, Shandong Provincial Key Laboratory of Pathogenesis and Prevention of Neurological Disorders and State Key Disciplines: Physiology, Medical College of Qingdao University, Qingdao, China and [2]Department of Molecular and Cellular Pharmacology, State Key Laboratory of Natural and Biomimetic Drugs, Peking University School of Pharmaceutical Sciences, Beijing, China

The gut-derived orexigenic peptide hormone ghrelin enhances neuronal firing in the substantia nigra pars compacta (SNc), where dopaminergic neurons modulate the function of the nigrostriatal system for motor coordination. However, how ghrelin regulates the excitability of dopaminergic neurons remains unknown. Here we describe a novel mechanism by which ghrelin enhances firing of nigral dopaminergic neurons by inhibiting voltage-gated potassium Kv7/KCNQ/M-channels through its receptor GHS-R1a-activated PLC-PKC pathway. Brain slices of the SNc were prepared from SD rats of postnatal 10 days. Nystatin-perforated patch clamp recordings of SNc neurons reveal that ghrelin inhibits native Kv7/KCNQ/M-currents from 25.4 ± 3 pA to 12.1 ± 2.1 pA (n=8, $p<0.01$, Values are means ± S.E.M., compared by Paired t-test.). This effect is abolished by selective inhibitors of GHS-R1a, PLC and PKC. Transgenic suppression of native Kv7/KCNQ/M-channels in mice (6-7-week old rQ2-G279S transgenic mice with background of TB6D2F1/Crl * C57/B6) or channel blockade with XE991 abolishes ghrelin-induced hyperexcitability. In vivo, adult female Wistar rats weighing 200-250 g were anesthetized with chloral hydrate (400 mg/kg, i.p.). Intracerebroventricular ghrelin administration (100 nM or 1000 nM, 5 μl) causes increased dopamine release from 1.3 ± 0.2 μM to 3.9 ± 0.5 μM (n=6, $p<0.05$, Values are means ± S.E.M.) and turnover (n=6, $p<0.05$) in the striatum. Microinjection of ghrelin (1000 nM, 0.5 μl) or XE991 (1 μM, 0.5 μl) into SNc results in contralateral dystonic posturing, and attenuation of catalepsy elicited by systemic administration of the D2 receptor antagonist haloperidol. Taken together, our findings reveal that ghrelin exerts its function by inhibiting voltage-gated Kv7/KCNQ/M-channel, resulting in enhanced excitability of nigral dopaminergic neurons for improvement of motor impairment. The ghrelin/KCNQ signaling is likely a common pathway utilized by the nervous system.

PCA134

Neurorescue effect of rosmarinic acid on 6-hydroxydopamine-lesioned nigral dopamine neurons in rat model of Parkinson's disease

J. Wang[2], H. Xu[1], H. Jiang[1], X. Du[1], P. Sun[2] and J. Xie[1]

[1]Department of Physiology, Shandong Provincial Key Laboratory of Pathogenesis and Prevention of Neurological Disorders and State Key Disciplines: Physiology, Medical College of Qingdao University, Qingdao, China and [2]Department of Neurosurgery, the Affiliated Hospital of Medical College, Qingdao University, Qingdao, China

Rosmarinic acid (RA) is a naturally occurring polyphenolic compound. It has been reported that RA possessed antioxidant and anti-inflammatory properties. Our previous study showed that RA could protect MES23.5 dopaminergic cells against 6-hydroxydopamine (6-OHDA)-induced neurotoxicity in vitro. The purpose of this study was to explore the neuroreparative (neurorescue) effect of RA on 6-OHDA-lesioned rat model of Parkinson's disease (PD) in vivo. In this study, female Wistar rats weighing 200–220 g were given 20 mg/kg RA by intragastric administration from day 1 after 6-OHDA lesioning and continued till the 21st day. Results showed that the dopamine content in the striatum decreased (n=6, $p<0.05$) and the numbers of tyrosine hydroxylase-immunoreactive neurons reduced after 6-OHDA treatment (n=6, $p<0.01$). RA treatment after 6-OHDA administration could restore these changes. Further studies demonstrated that 6-OHDA treatment increased the iron-staining positive cells, which were markedly decreased by RA treatment (n=6, $p<0.01$). Moreover, RA suppressed the increased ratio of Bax/Bcl-2 at gene level induced by 6-OHDA (n=6, $p<0.01$). This indicates that the neurorescue effects of RA against 6-OHDA-induced degeneration of the nigrostriatal dopaminergic system were achieved by decreasing nigral iron levels and regulating the ratio of Bcl-2/Bax gene expression.

PCA135

6-Hydroxydopamine upregulates iron regulatory protein 1 by activating certain protein kinase C isoforms in the dopaminergic MES23.5 cell line

W. Wang, N. Song, H. Zhang, J. Xie and J. Wang

Department of Physiology, Shandong Provincial Key Laboratory of Pathogenesis and Prevention of Neurological Disorders and State Key Disciplines: Physiology, Medical College of Qingdao University, Qingdao, China

Iron-induced oxidative stress is thought to play a crucial role in the pathogenesis of Parkinson's disease. Our previous studies demonstrated that decreased expression of ferroportin 1 contributes to 6-hydroxydopamine induced intracellular iron

accumulation and that decreased ferroportin 1 expression is caused by increased expression of iron regulatory protein 1. Iron regulatory protein 1 is a central regulator of iron homeostasis and is a likely target of extracellular agents to program changes in cellular iron metabolism. Therefore, the mechanism of iron regulatory protein 1 upregulation induced by 6-hydroxydopamine has become a significant focus of research. Iron regulatory protein 1 is regulated by protein kinase C, although this regulation is tissue specific. Therefore, in the present study, we aimed to determine whether alteration of protein kinase C activity modified iron regulatory protein 1 expression in the dopaminergic MES23.5 cell line. Furthermore, we investigated whether 6-hydroxydopamine induced iron regulatory protein 1 upregulation is mediated by protein kinase C, thus achieving regulation of cellular iron levels. The results showed that iron regulatory protein 1 was upregulated by phorbol 12-myristate-13-acetate, the PKC activator in dopaminergic MES23.5 cells, and ferroportin 1 expression and iron efflux were decreased as a result of iron regulatory protein 1 upregulation. The protein kinase C inhibitor bisindolylmaleimide I hydrochloride abolished the effect of phorbol 12-myristate-13-acetate. Protein kinase C-δ and protein kinase C-ζ, but not protein kinase C-ε were activated by 6-hydroxydopamine. The protein kinase C-δ inhibitor rottlerin inhibited protein kinase C-δ phosphorylation and abolished iron regulatory protein 1 upregulation induced by 6-hydroxydopamine. The protein kinase C-ζ pseudo-substrate inhibitor inhibited protein kinase C-ζ phosphorylation and abolished iron regulatory protein 1 upregulation induced by 6-hydroxydopamine. These data indicate that iron regulatory protein 1 is regulated by protein kinase C in dopaminergic MES23.5 cells and that protein kinase C activated by 6-hydroxydopamine regulates iron regulatory protein 1 expression, thus achieving regulation of cellular iron levels.

We thank Dr. Wei-Dong Le for providing us the MES23.5 cell line. This work was supported by grants from the National Basic Research Program of China (2011CB504102), the National

HO-1 participates differentially in astroglia and neurons vulnerability

X. Yu, N. Song, H. Jiang and J. Xie

Department of Physiology, Shandong Provincial Key Laboratory of Pathogenesis and Prevention of Neurological Disorders and State Key Disciplines: Physiology, Medical College of Qingdao University, Qingdao, China

Over expression of heme oxygenase-1 (HO-1) was observed in both astroglia and neurons in the substantia nigra pars compacta of patients with Parkinson's disease (PD). However, the role of HO-1 in PD pathogenesis remains unknown. To determine whether and how HO-1 participates differentially in astroglia and neurons vulnerability, we first analyzed time-dependent HO-1 expression induced by 1-methyl-4-phenyl-pyridinium (MPP+) and alpha-synuclein in primary cultured mesencephalic astroglia and neurons. The results showed that both toxins induced a time-dependent HO-1 up-regulation in these cells, however, neuronal HO-1 up-regulation appeared much later than glial. We further demonstrated that HO-1 inhibitor zinc protoporphyrin aggravated MPP+ induced oxidative damage in both astrocytes and neurons, indicating this HO-1 response was cyto-protective. Overexpression of HO-1 induced by activator cobalt protoporphyrin (copp) showed protective effects on neurons in the time of inadequate HO-1 up-regulation, however, aggragates MPP+ induced oxidative damage at the peak of HO-1 response. For astroglia, copp always showed dose-dependent protective effects. These results indicate that between astrogila and neurons, HO-1 was differentially modulated in a time-dependent manner and over-expressed HO-1 might play different roles in cellular antioxidation.

Presynaptic glutamine transport sustains glutamatergic transmission at a mammalian central synapse

B. Billups, M. Marx and D. Billups

Department of Pharmacology, University of Cambridge, Cambridge, UK

Glutamate is the main excitatory neurotransmitter in the mammalian CNS. It has been proposed that presynaptic terminals sequester glutamine from the extracellular fluid to replenish synaptically released glutamate. Using direct electrophysiological recordings from the calyx of Held presynaptic terminal, we investigated the nature of the presynaptic glutamine transport mechanism and assessed its role in maintaining glutamatergic synaptic transmission.

Brainstem sections containing the medial nucleus of the trapezoid body (MNTB) were obtained from P10-15 Wistar rats. Presynaptic terminals were whole-cell voltage-clamped and glutamine transporter currents were elicited by 5 s puff-application of 10 mM glutamine from an adjacent pipette. Values are means ± S.E.M., compared by ANOVA.

In quiescent presynaptic terminals the glutamine induced current (I_{gln}) was almost absent (-0.7 ± 0.4 pA; n=17). However, activation of Ca^{2+} currents in the presynaptic terminal by depolarisation (-80 to 0 mV for 2 ms, repeated at 100 Hz for 2 s) consistently resulted in the rapid establishment of a robust I_{gln} (-12.9 ± 1.6 pA; n=24). The induction of I_{gln} was blocked by the removal of external Ca^{2+} (by 93 ± 3 %; n=3; $p<0.001$) and was inhibited by inclusion of botulinum neurotoxin C in the patch-pipette (by 57 ± 2 %; n=3; $p<0.05$), indicating the involvement of vesicle fusion. Cessation of presynaptic stimulation resulted in down-regulation of I_{gln} with a half-time of <30 s. Furthermore, I_{gln} was eliminated by the removal of external Na^+ (by 99 ± 1%; n=3; $p<0.001$) and by the specific system A neutral amino acid transport inhibitor α-methyl-aminoisobutyric acid (MeAIB; reduced by 94 ± 3 %; n=3; $p<0.001$). At depolarised potentials I_{gln} did not reverse, consistent with activation of a transporter. Additionally, puff application of 200 μM glutamate did not induce a significant membrane current (0.0 ± 0.5 pA;

n=3; p<0.05), indicating a lack of direct presynaptic glutamate uptake.
Miniature EPSCs recorded from the postsynaptic MNTB principal neurons (-38.8 ± 3.5 pA) were inhibited by MeAIB (-28.6 ± 3.4 pA; n=5; p<0.01) following stimulation at 200 Hz to promote turnover of the presynaptic glutamate pool. Single EPSCs in the absence of high frequency stimulation were unaffected by MeAIB (-4.5 ± 0.5 nA in control and -4.3 ± 0.4 nA in MeAIB; n=3 p=0.4), indicating that MeAIB does not have a direct effect on postsynaptic AMPA receptors and is acting to reduce vesicular glutamate content.
These data indicate that system A mediated glutamine transport occurs in glutamatergic nerve terminals and that its functional expression in the presynaptic plasma membrane is dynamically controlled by synaptic activity. They also indicate that system A is important in maintaining the supply of glutamate for excitatory neurotransmission during periods of high frequency stimulation.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

PCA140

Infraslow (<0.5 Hz) brain potentials reflect different neurophysiologic mechanisms of sensory information neuroprocessing in the human brain

I.V. Filippov, A.A. Krebs and K.S. Pugachev

Physiology and Biophysics & Pathophysiology, Yaroslavl State Medical Academy, Yaroslavl, Russian Federation

OBJECTIVE: Our previous studies indicated that infraslow brain potential oscillations (ISO) in sensory cortical areas of rodents were involved in neuroprocessing of sensory information. The aim of this study was to analyze brain ISO over the projections of visual, auditory, and gustatory cortices in volunteers during application of corresponding sensory stimuli.
METHODOLOGY: This work was conducted in adherence with the World Medical Association's Declaration of Helsinki. Fifteen volunteers with the age of 24-41 (n=30 experiments) were included in this study. Surface Ag/AgCl electrodes were placed in the positions Fp1, T3, and O1 in accordance with 10-20 EEG scheme. ISO were recorded using computer EEG data acquisition/stimulation system. ISO were recorded over projections of visual cortex under condition of darkness (0 lx) and during rhythmic photic stimulation (0-1500 lx, 5 Hz, flash duration 40 ms); over projections of auditory cortex under condition of silence and during rhythmic acoustic stimulation (clicks, 40 dB SPL, 1000 Hz tone); over projections of frontal cortex under application of distilled water, 0.55 M glucose and 0.155 M NaCl solutions. Power spectral analysis was used to evaluate ISO dynamics, for statistics we used one-way ANOVA, and an alpha level of P<0.01 was adopted for all significance tests.
RESULTS: There were found complex ISO dynamics in Fp1, T3, and O1 in all recordings, this consisted of: waves in the domain of seconds (0.1-0.25 Hz), multisecond oscillations (0.0167-0.035 Hz), fluctuations in the range of minutes (<0.004 Hz) and millivolt scale potential (+/-20 mV). Statistically significant spectral alterations (as increase of powers of waves in the domain of seconds) were detected in O1 and T3 recordings under rhythmical photic and acoustic stimulations, respectively (compared to ISO dynamics under the condition of darkness and silence there). Stimulus-dependent taste ISO responses were identified in Fp1 recordings again in the range of seconds. There were present clear multisecond oscillation changes (however, different and opposite in their directions in O1, T3, and Fp1 recordings) under exposure of visual, acoustic and gustatory stimuli, although we have not found any statistically significant changes of fluctuations in the domain of minutes and millivolt scale potential under all experimental conditions.
CONCLUSIONS: Obtained data are strikingly similar to what was documented by us in rodents. Altogether, these allow us to conclude that infraslow brain potentials of different frequency domains reflect various neurophysiologic mechanisms of sensory information neuroprocessing in the human brain. Possible clinical implications of these results and this methodology should be strongly considered.

Characterization of hypoxia inducible factor pathway in neuroprotection and neurorestoration following cerebral ischaemia

R. Chen[1], S. Nagel[2], M. Papadakis[3], C. Schofield[4], P. Ratcliffe[5], C. Pugh[5] and A. Buchan[3]

[1]School of Pharmacy, Keele University, Newcastle under lyme, UK, [2]Department of Neurology, University of Heidelberg, Heidelberg, Germany, [3]Radcliffe Department of Medicine, University of Oxford, Oxford, UK, [4]Department of Chemistry, University of Oxford, Oxford, UK and [5]Wellcome Trust Center for Human Genetics, University of Oxford, Oxford, UK

Activation of the hypoxia inducible factors (HIF) pathway by inhibition of the HIF prolyl-4-hydroxylase enzymes (PHD) confers protection against ischemia/reperfusion injury (Sridharan V, et al. 2007). We investigated the precise function of each PHDs (1-3) in ischaemic stroke by using mice with each isoform genetically suppressed and by applying a novel specific PHD inhibitor – FG2216. Middle cerebral artery occlusion (MCAO)(45min ischaemia/24h reperfusion) was performed under anesthesia with 1.5% isoflurane in O2/N2O (1:3) on male, 8-12 week old PHD1-/-, PHD2+/- and PHD3-/- mice and their wild type (WT) littermates, as well as C57/B6 mice treated with FG2216. During the experiments, regional cerebral blood flow (rCBF) was recorded by a laser Doppler flowmetry. Behaviour was assessed at 24h after reperfusion with a common neuroscore. Infarct volumes, blood brain barrier (BBB) disruption, cerebral vascular density, reactive oxygen species (ROS) and apoptosis were then determined using histological and immunohistochemical techniques. When compared to their WT littermates, PHD2+/- mice had significantly more effective restoration of rCBF upon reperfusion, better functional outcomes (Neuroscores: 1.9±0.5 vs 4.3±0.5, p<0.01) and higher activity rates at 24h after MCAO, there were significantly fewer apoptotic cells in the penumbra and less BBB disruption, with a trend towards reduced infarct volume (26.7±6.7% vs 40±5.5%, p=0.15) but no difference in ROS formation; PHD3-/- mice had impaired rCBF upon early reperfusion but comparable functional outcomes; PHD1-/- mice did not show any significant changes following MCAO. When receiving FG2216 one day before the MCAO, C57/B6 mice had better neuroscores and smaller infarct volumes than those receiving the vehicle (Neuroscores: 2.0±0.6 vs 4.5±0.3; Infarct volumes: 27.0±8.1%

vs 47.4±5.3%, both p<0.05). No significant difference was seen in mice if receiving FG2216 immediately before the MCAO. Genetic inhibition of PHD enzymes produces different effects on outcome after transient cerebral ischemia. Notably, partially knock-out PHD2 confers neuroprotection for cerebral ischaemia. These effects are seen following lifelong PHD deficiency and thus reflect a composite of developmental changes, affecting features such as vessel density and overall sympathetic tone. While Fg2216 induces acute HIF activation amplifying the hypoxic stimuli inherent in this ischaemic/reperfusion model which could contribute to the observed protection. HIF activation upon ischaemic injury is swift, but the HIF transcription is delayed (Sharp FR, et al. 2004). Our study needs to be considered in optimizing therapeutic effects of PHD inhibitors, particularly when isoform specific inhibitors become available.

PCA142

Role of Rac1/NADPH oxidase in staurosporine-induced neurite outgrowth in PC12 cells

D. Kim, J. An, J. Kang and J. Seo

Yonsei University College of Dentistry, Seoul, Republic of Korea

Neurite outgrowth, which is the most distinct process during neuronal differentiation and regeneration, is an essential aspect of neuronal plasticity. PC12 cells have provided a number of clues about the signaling pathways involved in neurite outgrowth. PC12 cells differentiate into neuron-like cells in response to various stimuli, such as nerve growth factor (NGF) and staurosporine. The ERK signaling pathways play important roles in NGF-induced differentiation of PC12 cells. In contrast to NGF, however, the mechanism for staurosporine-induced neurite outgrowth is still unknown. In the present study, therefore, we examined the mechanisms by which staurosporine triggers neurite outgrowth. Images of living cells were obtained using a CCD camera and morphometric analysis was performed using Image-Pro Plus software. To assess direct modulation of Rac1 activity by staurosporine, the amount of cellular GTP-bound Rac1 was measured using the GST-PAK-CRIB binding assay. NADPH oxidase activity was measured by lucigenin chemiluminescence-based assay and the level of intracellular reactive oxygen species (ROS) was measured in cells loaded with DCF-DA using a confocal microscope. The statistical significance of differences between experimental groups was determined using an unpaired Student's t-test or one-way ANOVA and Bonferroni's test as appropriate. The results are expressed as means ± standard error of the mean (S.E.M.).

Staurosporine caused rapid neurite outgrowth independently of ERK signaling pathways. In contrast, neurite outgrowth in response to 100 nM staurosporine was accompanied by a 227.9 ± 23.9 % increase in Rac1 activity (p<0.05, n = 3), and the Rac1 inhibitor NSC23766 attenuated the staurosporine-induced neurite outgrowth in a concentration-dependent manner. In addition, suppression of Rac1 activity by expression of the dominant negative mutant Rac1N17 also blocked the staurosporine-induced neurite outgrowth of PC12 cells. Staurosporine caused a 75.4 ± 11.9 % increase in NADPH oxidase activity (p<0.05, n = 5) and increased the ROS production approximately by 150 ± 50 % (p<0.05, n = 5), which was prevented by NSC23766 and diphenyleneiodonium (DPI), an NADPH oxidase inhibitor. Pretreatment of cells with DPI attenuated the staurosporine-induced neurite outgrowth by 66.8 ± 4.2 % (p<0.05, n = 5) and exogenous addition of 100 μM H2O2 accelerated the 10 nM staurosporine-triggered neurite outgrowth by 92.3 ± 9.8 % (p<0.05, n = 7). These results indicate that activation of Rac1/NADPH oxidase, which leads to ROS generation, is required for neurite outgrowth induced by staurosporine in PC12 cells.

PCA143

Lidocaine unmasks L-type Ca^{2+} current-mediated action potentials in rat thalamocortical neurons

I. Putrenko[1,2] and S.K. Schwarz[2]

[1]Cellular and Physiological Sciences, The University of British Columbia, Vancouver, BC, Canada and [2]Anesthesiology, Pharmacology and Therapeutics, The University of British Columbia, Vancouver, BC, Canada

The mechanisms underlying the systemic central nervous system (CNS) toxicity of lidocaine are still largely obscure and not solely explained by its classic action on Na^+ channels. Here, we examined the hypothesis that Na^+ channel-independent actions of lidocaine in the thalamus, a brain area previously implicated as a site for lidocaine's systemic effects, contribute to its CNS toxicity. We investigated the effects of lidocaine at clinically CNS-toxic concentrations (100–600 μM) on firing properties of rat thalamocortical neurons in brain slices (250 μm) *in vitro*, using whole cell patch-clamp recording techniques. Brain slice preparations containing ventrobasal thalamic neurons were obtained from Wistar rats at postnatal days 13–16. Results are expressed as mean ± SEM and compared to control values by one-sample *t* tests, unless mentioned otherwise. Bath application of 100 μM lidocaine abolished typical tonic firing elicited in neurons current-clamped at –58 mV and evoked a distinct regular firing characterized by a more depolarized (higher) activation threshold (mean ± SD, –20.5 ± 8.4 mV vs. –44.3 ± 3 mV; $n = 12$; paired Student's t test, $P < 0.001$) and a different spike configuration. The high-threshold (HT) potentials disappeared completely when superfusing medium was either deprived of Ca^{2+} or contained the high voltage-activated Ca^{2+} channel blocker Cd^{2+} (50 μM). The specific L-type Ca^{2+} channel blocker, nifedipine, at 5 μM, but not at 1 μM, completely blocked the HT potentials, whereas the N-type Ca^{2+} channel blocker, ω-conotoxin GVIA (1 μM) had little effect on them. Neurons pretreated with tetrodotoxin (TTX, 600 nM), a tonic blocker of voltage-gated Na^+ channels, also exhibited regular firing of HT potentials. Their firing rate after reaching a maximum decreased in response to an increase in the magnitude of injected current due to the activation of a slowly recovering after-hyperpolarization (AHP) of the holding membrane potential. Application of lidocaine abolished the

AHP and caused neurons to respond to an increase in the magnitude of injected current with increased rate of HT firing. Furthermore, lidocaine, at 600 μM, increased input resistance in TTX-pretreated neurons by 86 ± 9% (n = 4; P < 0.001) and reduced the magnitude of current pulses required to trigger HT potentials by 24 ± 7% (n = 4; P < 0.05).

We conclude that lidocaine at clinically CNS-toxic concentrations unmasks Ca^{2+}-dependent HT action potentials mediated by L-type Cav1.2 channels. Inhibition by lidocaine of the hyperpolarization-activated mixed cationic current, I_h, and K^+ conductance(s) mediating slow AHPs[1], likely underlies its stronger unmasking effects compared to TTX. Overall, our findings support the notion that impaired Ca^{2+} homeostasis contributes to the complex and multifaceted mechanisms of supraspinal CNS toxicity of systemic lidocaine *in vivo*.

PCA144

Developmental changes of TRPV1 expression in C57BL/6 mice brain

W. Huang[1], F. Yu[2], X. He[1] and B. Peng[1]

[1]Physiolgoy, Wuhan University,Basic Medical Sciences, Wuhan, China and [2]Wuhan University, Zhongnan Hospital, Wuhan, Hubei, China

TRPV1 is a polymodel non-selective cation channel that can be activated by capsaicin, pH, heat and other noxious stimuli. In the last few years, expression of trpv1 has been certified in variety tissue and apparented different with species. However, distribution of trpv1 in the CNS is still a controversial question.Increasing evidences has demonstrated important role of TRPV1 in central system diseases, however the functions of TRPV1 in the brain are still an open question. Tom Schilling revealed that TRPV1 cation channels may provide potential therapeutic targets to reduce microglia-induced oxidative stress in Alzheimer's disease (AD). Clinical data showed that TRPV1 mRNA and protein were up-regulated in the mesial temporal lobe epilepsy patients. Our research aims to detect the expression of TRPV1 in hippocampus and cortex on developmental brain in C57BL/6 mice and explore the potential drug therapeutic targets in the age-dependent diseases. Mice model was using differential development C57BL/6 mice: 2-week old (n=12), 4-week old (n=12), 8-week old (n=12) and 16-week old (n=12) mice, respectively corresponded to infancy, adolescence, adult stage and gerontic in human. Detecting the expression of TRPV1 mRNA and protein were respectively by qRT-PCR, western blotting and immunohistochemistry. Values are means ± S.E.M., compared by nonparametric tests. Our findings revealed that trpv1 channel express in both two brain regions in C57B/6 mouse showing age-dependent. Comparing to 2-week old mouse in hippocampus, the mRNA level of 4,8,16 weeks old mice are increased, the relative expression in those groups are enhanced separately by 1.93 fold,11.43 fold and 1.8 fold ($^*p<0.05$). In cortex, the difference multiple of 4,8,16 weeks old mice were about 2.66 fold, 3.02 fold and 2.21 fold compared to 2 weeks old mice, respectively. In addition, protein level of 4,8,16 weeks old mice in hippocampus and cortex from western blotting and immunohitochemistry both increased comparing to 2 weeks old mouse, in keeping with mRNA level both in hippocampus and cortex. These results indicated that TRPV1 expression in developing brain showed an age-dependence pattern, thus raised the possibility that TRPV1 may play a key role related to age and developing brain diseases. Our study provides a basis for further studies of TRPV1 as a possible newly pharmacology target for age-dependent diseases such as Alzheimer's disease, parkinson's disease, age-dependent epileptic encephalopathy and febrile seizures.

PCA145

Glucagon-like peptide-1 and exendin-4 change neuronal excitability by modulating currents through $GABA_A$ channels

S. Korol, Z. Jin and B. Birnir

Department of Neuroscience, Uppsala University, Uppsala, Sweden

GABA signaling plays an important role in the regulation of neuronal activity in the mammalian brain. The hippocampus has a high density of receptors for metabolic hormones (Lathe, 2001) which may affect neuronal excitability. It has been shown that insulin influences GABA signaling in the hippocampus (Wan et al., 1997, Jin et al., 2011). Glucagon-like peptide-1 (GLP-1) is another metabolic hormone, secreted by intestinal L-cells, that affects brain function (During et al., 2003, Acuna-Goycolea and van den Pol, 2004). We have examined whether GLP-1 and its analog exendin-4 (Ex-4) can modulate GABA-evoked responses and neuronal excitability in CA3 pyramidal neurons of the rat hippocampus. We used the whole-cell patch-clamp technique in voltage-clamp or current-clamp mode to record GABA-activated currents or change in the membrane potential and action potential (AP) frequency in hippocampal slices from 16–20 days old Wistar rats. Administration of GLP-1 (10 pM–10 nM) or Ex-4 (10–100 nM) evoke tonic GABA-activated currents and increased the frequency of synaptic GABA-activated currents as compared to control. Values are means ± S.E.M., compared by ANOVA. In control conditions tonic currents were 3.3 ± 4.4 pA (n = 5) and were about ten times larger after application of 100 nM Ex-4 (33.8 ± 5.6 pA; n = 5; P < 0.001). The frequency of synaptic GABA-induced currents increased by 96 ± 35 % when neurons were exposed to 10 nM Ex-4 (n = 5; P < 0.05). AP firing frequency decreased and neuronal membrane potential hyperpolarized upon GLP-1 application. When GLP-1 has been washed away membrane potential depolarized back to the initial value (Fig. 1). Our results demonstrate that GLP-1 and Ex-4 enhance GABA signaling that leads to decreased neuronal excitability in rat hippocampal CA3 pyramidal neurons.

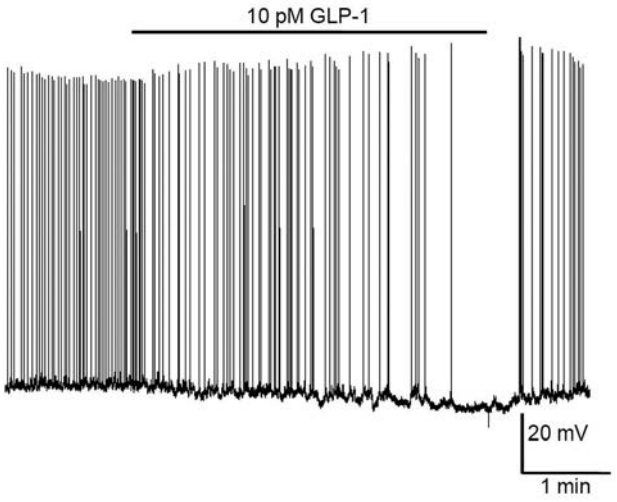

Figure 1. GLP-1 hyperpolarizes the membrane potential and decreases action potential frequency in CA3 pyramidal neurons of the rat hippocampus.

PCA146

Long-term potentiation of excitatory synaptic transmission from primary afferents or descending inputs to neonatal rat spinal cord motoneurons in vitro

M. Wang, Y. Su, X. Jiang, J. Jin, H. Zhang, H. Luo and Y. Zhang

Cell Electrophysiology Laboratory, Wannan Medical College, Wuhu, Anhui Province, China

In an in vitro spinal cord preparation, our previous study and other reports have identified excitatory postsynaptic potentials (EPSPs) in motoneurons (MNs) evoked by ipsilateral dorsal root (iDR)[1], ipsilateral ventrolateral funiculus (iVLF)[2,3], and contralateral VLF (cVLF)[4] stimulation, i.e. iDR-EPSPs, iVLF-EPSPs and cVLF-EPSPs, respectively. But the long-term synaptic plasticity in these synaptic transmissions has been little studied yet. In the present study, the intracellular recordings were performed from MNs in neonatal rat (8-14 days old) spinal cord slices prepared by the previously described procedures under anaesthetized state with ether [5], and membrane electrical parameters were observed. By monitoring the multi-parameter changes of EPSPs after tetanic stimulation on iDR, iVLF or cVLF, efficiency of the excitatory synaptic transmission to MNs were estimated. The increase in EPSP amplitude to more than 120% of control level and at least for 30 min could be referred to as long-term potentiation (LTP). After tetanic stimulation on iDR in 26 MNs, LTP of iDR-EPSPs (i.e. iDR-LTP) was observed in 17 cells, without increase in amplitude of iVLF-EPSPs recorded simultaneously in the same MNs (n=15). Moreover, some relevant changes such as the increase of area under curve, the prolonging of duration and the shortening of latency of iDR-EPSPs but not of iVLF-EPSPs in 15 tested MNs were comparably noted during the iDR-LTP. Similarly, the tetanic stimulation on iVLF and cVLF induced LTP of iVLF-EPSP (iVLF-LTP) in 11 cells of 33 tested MNs, and of cVLF-EPSP (cVLF-LTP) in 2 MNs, respectively. It was also noted that in one MN with cVLF-LTP, the simultaneously recorded iDR-EPSPs were potentiated to reach the criteria for LTP either, suggesting a heterosynaptic LTP. Among 9 tested MNs with iVLF-LTP, the paired-pulse facilitation ratios of amplitude of iVLF-EPSPs elicited by paired-pulse stimulation were different from the baseline in 7 MNs. Considered as a whole, there were no significant changes in the membrane electrical parameters of the tested MNs following induction of LTP. These preliminary data suggest that there may be some forms of LTP in excitatory synaptic transmission from peripheral afferents and descending fibers to MNs in the spinal cord, and it could be considered as a candidate of neural basis underlying the ability of motor learning.

PCA147

The Angelman syndrome protein Ube3a regulates synapse development by ubiquitinating Tkv in *Drosophila*

A. Yao, W. Li, H. Zhi, Y. Zhang and K. Kaur

The Institute of Genetics and Developmental Biology of the Chinese Academy of Sciences, Beijing, China

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe mental retardation, motor dysfunction, lack of speech, ataxia and developmental delay. It is caused by the absence of ubiquitin ligase Ube3a which is involved in protein degradation through the ubiquitin-associated proteasome-mediated pathway. Ube3a was also associated with autism spectrum disorder. However, little is known about how the loss-of-function of ube3a results in the pathogenesis of AS. Drosophila has a unique homolog of Ube3a, encoded by ube3a. We found that the number of both total boutons and satellite boutons in ube3a mutants was significantly increased compared with wild type. FM1-43 dye-load-

ing assay showed that ube3a mutants had an endocytosis defect in the NMJ synapses. Furthermore, electrophysiological analysis under high-frequency stimulation showed compromised neurotransmission in ube3a mutant synapses, confirming an insufficient replenishment of synaptic vesicles. These data suggest that ube3a regulates synapse morphology and function. Genetic interaction showed that heterozygous mutants of tkv, encoding the BMP receptor thickveins, rescued the synapse phenotype of ube3a mutants. Immunochemical analysis showed Tkv expression level was increased in ube3a mutants. Co-IP experiments showed that Tkv and Ube3a are present in a complex. Tkv can be ubiquitinated by Ube3a in S2 cells. Interestingly, overexpression of Ube3a also led to an increased number of total boutons and satellite boutons and increased Tkv protein level, suggesting that proper level of Ube3a is critically important for the normal synapse development. Our results suggested that Ube3a regulates BMP signaling pathway to control synapse development. These may partialy accounted for the pathological mechanism of Angelman syndrome.

Where applicable, the authors confirm that the experiments described here conform with The Physiological Society ethical requirements.

Presynaptic Ca^{2+} regulates many processes related to neurotransmission including synaptic vesicle (SV) release and endocytosis. However, the role of Ca^{2+} in other aspects of presynaptic function is incompletely understood. Furthermore, the repertoire of Ca^{2+} channels functioning at the synapse remains unknown. In a screen evaluating the roles of TRP channels in *Drosophila* larval neuromuscular junction function and development, we found that the TRPV channel, Inactive (Iav), functions presynaptically to regulate both synaptic growth and SV release probability. We found that the Iav-deficient (*mut*) synapses have a reduced number of presynaptic boutons (number of boutons, *mut* = 33.8±2.4, wild-type (*wt*) = 67.7±4.1, $p<0.05$, all data presented as mean ±SEM and analyzed by ANOVA hereafter) and a concomitant increase in bouton size (bouton volume, *mut* = 320.6 ±74.9 μm^3, *wt* = 142.2±31.5, $p<0.05$). Biochemical and high-resolution imaging experiments revealed that the mutant boutons were characterized by diminished microtubule polymerization (polymerized microtubule percentage, *mut* = 6.6±0.02%, *wt* = 20±0.02, $p<0.05$). Furthermore, we found that calcineurin A1 (CanA1) deficient synapses displayed similar phenotypes. More importantly, expression of constitutively active CanA1 in Iav-deficient motor neurons suppressed the growth defects (bouton number, *mut* expressing CanA1 = 61.2±1.9, *mut* control = 42.9±1.6, $p<0.05$). These data indicate that CanA1 stabilizes microtubules downstream of Iav. Remarkably, expressing human TRPV1 in the Iav-deficient motor neurons rescued the synaptic growth phenotypes (bouton number, *mut* expressing TRPV1 = 67.7±3.2, *mut* controls = 43.3±2.5, $p<0.05$). Examination of the subcellular distribution of Iav and TRPV1 in the motor neurons revealed that both proteins were localized to ER. Furthermore, we found that Iav regulates resting Ca^{2+} levels in motor axon terminals, and the loss of Iav results in a decrease in the amplitudes of evoked excitatory junction potentials (EJP) (*mut* = 12.4±1.1 mV, *wt* = 25.8±2.7, $p<0.05$). Further studies revealed that the SV release probability was markedly diminished in the absence of Iav, and this decrease in release probability underlies the decreased EJP amplitude. Indeed, elevating extracellular Ca^{2+} levels to increase SV release probability suppressed the EJP defect. Interestingly, overexpression of Iav increased SV release probability and EJP amplitudes. Thus, Iav is both necessary and sufficient to determine SV release and function, indicative of the vital role of the protein in neurotransmission. In summary, by releasing ER Ca^{2+}, Iav serves two physiologically distinct and separable functions. First, it regulates synaptic architecture and growth by promoting microtubule polymerization. Second, it determines SV release probability and the strength of synaptic transmission.

The over-expression of TNF-α differentially modulates the synaptic connection in hippocampus and in spinal dorsal horn following peripheral nerve injury

X. Liu, W. Ren, Y. Liu, J. Wang and L. Zhou

Department of Physiology, Zhongshan Medical School of Sun Yat-Sen University, Guangzhou, China

Around 2/3 chronic pain patients suffer from memory deficits and underlying mechanisms are unclear. We have shown that over-expression of TNF-αproduced by spared nerve injury (SNI) leads to both neuropathic pain and impairment of short-term memory (Ren, et al., 2011). In the present work with whole-cell patch-clamp electrophysiology and a single-neuron staining by an intracellular injection of biocytin for morphological analysis, we found that SNI reduced the synaptic connection and NMDA receptor current in hippocampal CA1 pyramidal neurons but increased them in NK-1-positive projection neurons in superficial spinal dorsal horn, and the effect was prevented by genetic deletion of TNFR1. TNF-α mimicked the effect of SNI in cultured hippocampal and spinal cord slices. Mechanistically, brain derived neurotrophic factor (BDNF), which is critical for synaptic formation and plasticity, was down-regulated in hippocampus but up-regulated in spinal dorsal horn following SNI. TNF-α also has the similar effect on BDNF expression in cultured hippocampal and spinal cord slices. Thus, the differential change in synaptic structure and function in hippocampus and in spinal dorsal horn may underlie chronic pain and the memory deficits following peripheral nerve injury. The opposite regulation of BDNF by TNF-αmay be critical for pathological process.

Serotonin-induced presynaptic inhibition of GABAergic transmission onto cholinergic neurons in the rat basal forebrain

T. Momiyama[1] and T. Nishijo[1,2]

[1]Department of Pharmacology, Jikei University School of Medicine, Tokyo, Japan and [2]Department of Pharmacology, Keio University School of Pharmacy, Tokyo, Japan

A Whole-cell patch-clamp study was carried out to elucidate modulatory roles of serotonin (5-HT) in GABAergic transmission onto basal forebrain cholinergic neurons, using brain slice preparations obtained from P12-19 rat under deep anesthesia with halothane. Animal handling and all experimental procedures were done according to the Guiding Principles for the care and Use of Animals in the Field of Physiological Sciences of the Physiological Society of Japan (2009), the UK Animals (Scientific Procedures) Act 1986, and the guidelines of Jikei University School of Medicine. GABAA receptor-mediated inhibitory postsynaptic currents (IPSCs) were evoked by focal electrical stimulation in the presence of CNQX, D-AP5 and strychnine to block non-NMDA-, NMDA- and glycine receptor-mediated currents components, respectively. Bath application of 5-HT reduced the amplitude of the evoked GABAergic IPSCs in a concentration-dependent manner between 0.1-100 μM The inhibition of IPSCs by 0.1, 1, 10 and 100 μM 5-HT was 21.1 ± 9.17 % (n=6), 35.2 ± 5.52 % (n=5), 58.5 ± 2.36 % (n=41) and 64.1 ± 5.46 % (n=4), respectively. A 5-HT1B receptor agonist, CP93129 (10 μM) also suppressed the IPSCs by 59.8 ± 9.25 % (n=5), whereas a 5-HT1A receptor agonist, 8-OH-DPAT, had no effect. NAS-181, a 5-HT1B receptor antagonist antagonized the 5-HT-induced suppression of IPSCs, whereas NAN-190, a 5-HT1A receptor antagonist did not. 5-HT (1 μM) reduced the frequency of spontaneous miniature IPSCs (mIPSCs) by 52.0 ± 9.85 % (n=6) without changing their amplitude distribution. This effect remained unchanged when extracellular Ca2+ was replaced by Mg2+ (5 mM). In the presence of ω-Aga-TK, ω-CgTX, or SNX-482, an N-, P/Q- or R-type calcium channel blocker, respectively, 5-HT could still inhibit the IPSCs. These findings suggest that activation of presynaptic 5-HT1B receptors on the terminals of GABAergic afferents to basal forebrain cholinergic neurons inhibits GABA release in Ca2+-independent manner.

A role for whirlin in proprioceptor mechanotransduction

J. de Nooij[1], A. Simon[2], S. Doobar[1], K.P. Steel[3], T. Jessell[1], R.W. Banks[4] and G.S. Bewick[2]

[1]Department of Biochemistry & Molecular Biophysics, Columbia University, New York, NY, USA, [2]School of Medical Sciences, University of Aberdeen, Aberdeen, UK, [3]Wolfson Centre for Age-Related Diseases, King's College London, London, UK and [4]School of Biological & Biomedical Sciences, University of Durham, Durham, UK

Information on muscle length and tension are essential for the central nervous system to determine the position of body and limbs in space. This is a necessary prerequisite for co-ordinated motor behaviour. This proprioceptive sense is mediated by specialised mechanoreceptors located within the muscle: the muscle spindle (responsive to changes in muscle length) and Golgi tendon organs (responsive to changes in muscle tension). Anatomical and physiological analysis have provided many insights into the properties of the proprioceptor muscle afferents that innervate these mechanoreceptors but the molecular mechanisms that underlie the mechanotransduction process remains largely unknown. Here we show that the PDZ – scaffold protein Whirlin is expressed in proprioceptor neurones in dorsal root ganglia and localises to their peripheral sensory endings. Whirlin mutations have previously been implicated in abnormalities of hair cell and photoreceptor sensory transduction, particularly Usher syndrome (1), raising the possibility that Whirlin also functions in the proprioceptive mechanotransduction process. Recording afferent nerve discharge from an *in vitro* mouse soleus muscle/nerve preparation, we find that the activation of spindle afferents by mechanical stretch is greatly diminished in *whirlin* (*wi*) mutant mice (2) compared to their wild-type (*wt*) littermates (33.6 ± 10.4 Hz, *10* v 106.2 ± 28.2 Hz, *6*; mean ± SE, *n*; $P<0.01$, paired t-test). Application of exogenous glutamate (1 μM) restores afferent excitability in response to stretch (111.1 ± 43.0 Hz, NS v *wt*). Amiloride (10 μM, an inhibitor of DEG/ENaC channels) and PCCG – 13 (1 μM, blocking atypical metabotropic glutamate receptors in mechanosensory endings (3)) reduced the glutamate-mediated enhancement in *wt* animals (from 205.1 ± 74.2 Hz to 95.4 ± 38.0 Hz, *4* (amil) & from 268.7 ± 37.9 Hz to 207.5 ± 43.8 Hz, *6* (PCCG); both $P<0.05$) but have comparatively less effect on the stretch – evoked spike frequency in *wi* mutants (to 99.8 ± 27.4 Hz, *6* & 93.2 ± 29.5 Hz, *8*; both NS v 1 μM glutamate). Together, these data indicate that essential components of proprioceptor mechanotransduction machinery are present but operate inefficiently in the absence of Whirlin function. Whirlin may serve to recruit and/or ensure the proper localisation of transduction molecules in proprioceptor sensory terminals.

Clathrin and its role in fast endocytosis in retinal bipolar cells and hippocampal neurons

M. Pasche[1], I. Pelassa[2], C. Zhao[3], B. Odermatt[4] and L. Lagnado[1]

[1]Neurobiology, MRC - LMB, Cambridge, UK, [2]Neuroscience Department, Universita' di Torino, Turin, Italy, [3]Southwest Eye Hospital - Lab of Neurobiology, Third Military Medical University, Chong Qing, China and [4]Neuroanatomie, Rheinische Friedrich-Wilhelms-Universität, Bonn, Germany

The classical mode of clathrin-mediated endocytosis in non-neuronal cells occurs on the time-scale of a minute while retrieval of synaptic vesicles usually occurs 1-10 s after fusion. To investigate the molecular dynamics of fast endocytosis, we applied dual-colour total internal reflection fluorescence and confocal microscopy to ribbon synapses of retinal bipolar cells. These cells were derived from transgenic zebrafish expressing either combination of two of the following fluorescently labelled proteins: the fusion reporter sypHy, clathrin-eGFP/mCherry and/or the synaptic ribbon marker ribeye-mCherry.
